The CME Text ‘Guidelines on Diabetes, pre-diabetes and cardiovascular diseases’ is accredited by the European Board for Accreditation in Cardiology (EBAC) for ‘2’ hours of External CME credits. Each participant should claim only those hours of credit that have actually been spent in the educational activity. EBAC works according to the quality standards of the European Accreditation Council for Continuing Medical Education (EACCME), which is an institution of the European Union of Medical Specialists (UEMS). Incompliance with EBAC/EACCME guidelines, all authors participating in this programme have disclosed potential conflicts of interest that might cause a bias in the article. The Organizing Committee is responsible for ensuring that all potential conflicts of interest relevant to the programme are declared to the participants prior to the CME activities.

The content of these European Society of Cardiology (ESC) Guidelines has been published for personal and educational use only. No commercial use is authorized. No part of the ESC Guidelines may be translated or reproduced in any form without written permission from the ESC. Permission can be obtained upon submission of a written request to Oxford University Press, the publisher of the European Heart Journal and the party authorized to handle such permissions on behalf of the ESC.

Disclaimer. The ESC Guidelines represent the views of the ESC and were arrived at after careful consideration of the available evidence at the time they were written. Health professionals are encouraged to take them fully into account when exercising their clinical judgement. The guidelines do not, however, override the individual responsibility of health professionals to make appropriate decisions in the circumstances of the individual patients, in consultation with that patient, and where appropriate and necessary the patient’s guardian or carer. It is also the health professional’s responsibility to verify the rules and regulations applicable to drugs and devices at the time of prescription.

Preamble

Guidelines and Expert Consensus documents aim to present management and recommendations based on all of the relevant evidence on a particular subject in order to help physicians to select the best possible management strategies for the individual patient, suffering from a specific condition, taking into account not only the impact on outcome, but also the risk–benefit ratio of a particular diagnostic or therapeutic procedure. Numerous studies have demonstrated that patient outcomes improve when evidence-based guideline recommendations are applied in clinical practice.

A great number of Guidelines and Expert Consensus Documents have been issued in recent years by the European Society of Cardiology (ESC) and also by other organizations or related societies. The profusion of documents can question the authority and credibility of guidelines, particularly if discrepancies appear between different documents on the same issue leading to confusion for practising physicians. In order to avoid these pitfalls, the ESC and other organizations have issued recommendations for formulating and issuing Guidelines and Expert Consensus Documents. The ESC recommendations for guidelines production can be found on the ESC website. It is beyond the scope of this preamble to recall all, but the basic rules.

In brief, the ESC appoints experts in the field to carry out a comprehensive review of the literature, with a view to making a critical evaluation of the use of diagnostic and therapeutic procedures, and assessing the risk–benefit ratio of the therapies recommended for management and/or prevention of a given condition. Estimates of expected health outcomes are included, where data exists. The strength of evidence for or against particular procedures or treatments is weighed, according to predefined scales for grading recommendations and levels of evidence, as outlined below.

The Task Force members of the writing panels, as well as the document reviewers, are asked to provide disclosure statements of all relationships they may have, which might be perceived as real or potential conflicts of interest. These disclosure forms are kept on file at the European Heart House, headquarters of the ESC and can be made available by written request to the ESC President. Any changes in conflict of interest that arise during the writing period must be notified to the ESC.

Guidelines and recommendations are presented in formats that are easy to interpret. They should help physicians to make clinical decisions in their daily routine practice, by describing the range of generally acceptable approaches to diagnosis and treatment. However, the ultimate judgement regarding the care of an individual patient must be made by the physician-in-charge of his/her care.

The ESC Committee for Practice Guidelines (CPG) supervises and coordinates the preparation of new Guidelines and Expert Consensus Documents produced by Task Forces, expert groups or consensus panels. The Committee is also responsible for the endorsement of these Guidelines and Expert Consensus Documents or statements.

Once the document has been finalized and approved by all the experts involved in the Task Force, it is submitted to outside specialists for review. In some cases, the document can be presented to a panel of key opinion leaders in Europe on the relevant condition, for discussion and critical review. If necessary, the document is revised once more and finally approved by the CPG and selected members of the Board of the ESC and subsequently published.

After publication, dissemination of the message is of paramount importance. Publication of executive summaries and the production of pocket-sized and PDA-downloadable versions of the recommendations are helpful. However, surveys have shown that the intended end-users are often not aware of the existence of guidelines, or simply do not put them into practice. Implementation programmes are thus necessary and form an important component of the dissemination of knowledge. Meetings are organized by the ESC, and directed towards its member National Societies and key opinion leaders in Europe. Implementation meetings can also be undertaken at a national level, once the guidelines have been endorsed by the ESC member societies, and translated into the local language, when necessary.

All in all, the task of writing Guidelines or Expert Consensus Documents covers not only the integration of the most recent research, but also the creation of educational tools, and implementation programmes for the recommendations. The loop between clinical research, writing of guidelines, and implementing them into clinical practice can then only be completed if surveys and registries are organized to verify that actual clinical practice is in keeping with what is recommended in the guidelines. Such surveys and registries also make it possible to check the impact of strict implementation of the guidelines on patient outcome.

Introduction

Diabetes and cardiovascular diseases (CVD) often appear as the two sides of a coin: on one side, diabetes mellitus (DM) has been rated as an equivalent of coronary heart disease (CHD), and conversely, many patients with established CHD...
suffer from diabetes or its pre-states. Thus, it is high time that diabetologists and cardiologists join forces together to improve the quality management in diagnosis and care for the millions of patients who have both cardiovascular and metabolic diseases in common in one and the same person.

The cardio-diabetologic approach not only is of utmost importance for the sake of those patients, but also instrumental for further progress in the fields of cardiology and diabetology.

The European Society of Cardiology (ESC) and the European Association for the Study of Diabetes (EASD) have accepted this challenge and decided to develop joint, evidence-based guidelines for ‘Diabetes and Cardiovascular Diseases’. Experts from both sides were asked to form a Task Force and to write state-of-the-art chapters. Although individual authors have been assigned to draft the manuscripts according to their specific area of expertise, the guidelines were then extracted and harmonized as a true team effort by the whole group. Hence, the names of all authors appear only on the cover of these guidelines as members of the writing group. Some of the members of the Task Force were helped in the literature search and writing process by members of their respective teams and these contributors are also named on the cover as contributors. The guidelines were then reviewed by independent referees appointed by the two scientific organizations whose identity were disclosed, once all criticisms and suggestions had been incorporated into the text to achieve the broadest possible expertise and consensus. The referees are also acknowledged with their names on the cover and are an important, integral part of this scientific guideline exercise.

It may seem that these guidelines are rather extensive. They were, however, written for two ‘worlds’, diabetology and cardiology. Thus, information that may seem obvious, including pathophysiology, for one part may need a more extensive description for the other. A decision was therefore taken, to keep the main document as complete as possible, making an executive summary and pocket guidelines for those, who are searching short, practical information. These guidelines do not aim to provide detailed information on daily blood glucose management in patients because therapies are tailored to individual patient requirements, particularly in patients with type 2 diabetes. Achieving the agreed glucose level targets is more important than the therapy and regimen. For those requiring additional information on blood glucose management the Global Guideline for Type 2 Diabetes of the International Diabetes Federation (www.idf.org) is recommended.

The core approach of the group is depicted in Figure 1. An algorithm has been developed to help discover the alternate CVD in patients with diabetes, and vice versa, the metabolic diseases in patients with CHD, setting the basis for appropriate joint therapy. This algorithm has also been endorsed by the expert working group of the Declaration of Vienna on February 15, 2006 under the auspices of the Austrian Presidency of the European Union. The purpose of these guidelines is to improve the management of:

1. Patients with overt diabetes.
2. Patients at risk of developing diabetes, as demonstrated by impaired glucose tolerance.
3. Cardiovascular diseases in these patient populations.

The terms ‘primary prevention’ and ‘secondary prevention’ may not be quite appropriate in the case of diabetes, a high-risk situation in itself, but the terms are strongly consolidated and kept in this context when reasonable.

It is a great privilege for the two co-chairmen of this task force of having been able to work with the finest and best reputed experts and scientists in the field at the European level and to give these guidelines now to the community of cardiologists and diabetologists. On this occasion, we wish to thank all members of the task force who so generously shared their knowledge, as well as the referees for their tremendous input. Special thanks go to Professor Carl Erik Møgensen for his advice on the diabetic renal disease and microalbuminuria sections. We would also like to thank the ESC and the EASD for making these guidelines possible. Finally, we want to express our appreciation of the guideline team at the Heart House, especially Veronica Dean, for their extremely helpful support.

bLevel of evidence.
Introduction

DM is a metabolic disorder of multiple aetiology characterized by chronic hyperglycaemia with disturbances of carbohydrate, fat, and protein metabolism resulting from defects of insulin secretion, insulin action, or a combination of both. In type 1 diabetes, it is due to a virtually complete lack of endogenous pancreatic insulin production, whereas in type 2 diabetes, the rising blood glucose results from a combination of genetic predisposition, unhealthy diet, physical inactivity, and increasing weight with a central distribution resulting in complex pathophysiological processes. Traditionally, diagnosis of diabetes was based on symptoms due to hyperglycaemia, but during the last decades much emphasis has been placed on the need to identify diabetes and other forms of glucose abnormalities in asymptomatic subjects. DM is associated with development of specific long-term organ damage (diabetes complications) including retinopathy with potential blindness, nephropathy with risk for foot ulcers, amputation, and Charcot joints and autonomic dysfunction such as sexual impairment. Patients with diabetes are at a particularly high risk for cardiovascular, cerebrovascular, and peripheral artery disease.

Definition and classification of diabetes

Since the first unified classification of diabetes by the National Diabetes Data Group in 1979 and the World Health Organisation (WHO) in 1980, a few modifications have been introduced by the WHO4,5 and the American Diabetes Association (ADA)6,7 (Table 1).

Impaired glucose tolerance (IGT) can be recognized by the results of OGTT only: 2-h post-load plasma glucose (2hPG) ≥7.8 and <11.1 mmol/L (≥140 and <200 mg/dL).

A standardized OGTT test performed in the morning, after an overnight fast (8–14 h); one blood sample should be taken before and one 120 min after intake of 75 g glucose dissolved in 250–300 mL water in a course of 5 min (note: timing of the test is from the beginning of the drink).

Classification of diabetes includes both aetiological types and different clinical stages of hyperglycaemia as suggested by Kuzuya and Matsuda.8 Four main aetiological categories of diabetes have been identified as diabetes type 1, type 2, other specific types, and gestational diabetes, as detailed in the WHO document (Tables 2 and 3, Figure 2).

Type 1 diabetes characterized by deficiency of insulin due to destructive lesions of pancreatic β-cells; usually progresses to the stage of absolute insulin deficiency. Typically, it occurs in young subjects with acute-onset with typical symptoms of diabetes together with weight loss and propensity to ketosis, but type 1 diabetes may occur at any age, sometimes with slow progression. People who have antibodies to pancreatic β-cells such as glutamic-acid-decarboxylase (GAD), are likely to develop either typical acute-onset or slow-progressive insulin-dependent diabetes.10,11 Today antibodies to pancreatic β-cells are considered as a marker of type 1 diabetes, although such antibodies are not detectable in all patients.

Type 2 diabetes is caused by a combination of decreased insulin secretion and decreased insulin sensitivity. Typically, the early stage of type 2 diabetes is characterized by insulin resistance and decreased ability for insulin secretion causing excessive post-prandial hyperglycaemia. This is followed by a gradually deteriorating first-phase insulin response to increased blood glucose concentrations.12 Type 2 diabetes, comprising over 90% of adults with diabetes, typically develops after middle age. The patients are often obese or have been obese in the past and have typically been physically inactive. Hyperosmolarity is uncommon, but may occur in the presence of severe infection or severe stress.

Gestational diabetes constitutes any glucose perturbation that develops during pregnancy and disappears after delivery. Long-term follow-up studies, recently reviewed by Kim et al.,13 reveal that most, but not all, women with gestational diabetes do progress to diabetes after pregnancy. Long-term studies that have been conducted over a period of more than 10 years reveal a stable long-term risk of ~70%.13 In some cases, type 1 diabetes may be detected during pregnancy.

Other types include: (i) diabetes related to specific single genetic mutations that may lead to rare forms of diabetes, as for instance MODY; (ii) diabetes secondary to other pathological conditions or diseases (as a result of pancreatitis, trauma, or surgery of pancreas); (iii) drug or chemically induced diabetes.

The clinical classification also comprises different stages of hyperglycaemia, reflecting the natural history of absolute or relative insulin deficiency progressing from normoglycaemia to diabetes. It is not uncommon that a non-diabetic

Values are expressed as venous plasma glucose.

FPG = fasting plasma glucose; 2-h PG = two-hour post-load plasma glucose (1 mmol/L = 18 mg/dL).
individual may move from one category to another in either direction. Usually, a progression towards a more severe glucose abnormality takes place with increasing age. This is reflected by the increase in the 2-hPG level with age.14 The currently valid clinical classification criteria have been issued by WHO4 and ADA.7 These are currently under review by WHO and updated criteria will be introduced soon. The WHO recommendations for glucometabolic classification are based on measuring both fasting and 2-hPG concentrations and recommend that a standardized 75 g OGTT should be performed in the absence of overt hyperglycaemia.4 The thresholds for diabetes on fasting and 2-hPG values were primarily determined by the values where the prevalence of diabetic retinopathy, which is a specific complication of hyperglycaemia, starts to increase.

Even though macrovascular diseases such as CHD and stroke are major causes of death in type 2 diabetic patients and people with IGT, macrovascular disease has not been considered in the classification. This sounds illogical and may give an impression that macrovascular diseases are less important than microvascular consequences of diabetes.

Classification according to the ADA criteria strongly encourages the single use of fasting glycaemia only without an OGTT.6,7 The currently recommended categories of glucose metabolism according to WHO and the ADA are presented in Table 1 (for adults). The National Diabetes Data Group2 and WHO3 coined the term IGT, an intermediate category between normal glucose tolerance and diabetes. The ADA6 and the WHO Consultation4 proposed some changes to the diagnostic criteria for diabetes and introduced a new category called impaired fasting glucose/glycaemia (IFG). The ADA recently decreased the lower threshold for IFG from 6.1 to 5.6 mmol/L,7 but this has been criticized and has not yet been adopted by the WHO expert group that recommends to keep the previous cut-points as shown in the WHO consultation report in 1999. These criteria were reviewed by a new WHO expert group in 2005.

In order to standardize glucose determinations, plasma has been recommended as the primary specimen. Since many equipment use either whole blood or venous or capillary blood, thresholds for these vehicles have also been given. The non-plasma recommendations for threshold are based on approximate estimates rather than on validated conversion factors. A recent analysis based on the direct pair-wise comparison of various types of specimens suggest that the factors presented in Table 4 should be used to convert values measured in whole blood, capillary blood, and serum to plasma, respectively.15

The glucometabolic category in which an individual is placed depends on whether only fasting plasma glucose (FPG) is measured or if it is combined with a 2-hPG value. For example, an individual falling into the IFG category in the fasting state may have IGT or diabetes disclosed by a post-load glucose.

Classification according to the ADA criteria strongly encourages the single use of fasting glycaemia only without an OGTT.6,7

The currently recommended categories of glucose metabolism according to WHO and the ADA are presented in Table 1 (for adults). The National Diabetes Data Group2 and WHO3 coined the term IGT, an intermediate category between normal glucose tolerance and diabetes. The ADA6 and the WHO Consultation4 proposed some changes to the diagnostic criteria for diabetes and introduced a new category called impaired fasting glucose/glycaemia (IFG). The ADA recently decreased the lower threshold for IFG from 6.1 to 5.6 mmol/L,7 but this has been criticized and has not yet been adopted by the WHO expert group that recommends to keep the previous cut-points as shown in the WHO consultation report in 1999. These criteria were reviewed by a new WHO expert group in 2005.

In order to standardize glucose determinations, plasma has been recommended as the primary specimen. Since many equipment use either whole blood or venous or capillary blood, thresholds for these vehicles have also been given. The non-plasma recommendations for threshold are based on approximate estimates rather than on validated conversion factors. A recent analysis based on the direct pair-wise comparison of various types of specimens suggest that the factors presented in Table 4 should be used to convert values measured in whole blood, capillary blood, and serum to plasma, respectively.15

The glucometabolic category in which an individual is placed depends on whether only fasting plasma glucose (FPG) is measured or if it is combined with a 2-hPG value. For example, an individual falling into the IFG category in the fasting state may have IGT or diabetes disclosed by a post-load glucose.

The metabolic determinants and physiological bases of FPG and 2-hPG differ to some extent.1,16,17 This means the categorization of an individual on a FPG value may differ from that based on a 2-hPG. Having a normal FPG requires the ability to maintain an adequate basal insulin secretion and an appropriate hepatic insulin sensitivity to control

---

Table 2 Aetiological classification of glycaemia disorders

| Type 1 (β-cell destruction, usually leading to absolute insulin deficiency) | Autoimmune | Idiopathic |
| Type 2 (may range from predominantly insulin resistance with relative insulin deficiency to a predominantly secretory defect with or without insulin resistance) | Genetic defects of β-cell function | Genetic defects in insulin action | Diseases of the exocrine pancreas | Endocrinopathies | Drug- or chemical-induced infections | Other genetic syndromes sometimes associated with diabetes, e.g.: Down’s syndrome, Friedreich’s ataxia, Klinefelter’s syndrome, Wolfram’s syndrome | Gestational diabetes |

As additional subtypes are discovered, it is anticipated that they will be reclassified within their own specific category.

Includes the former categories of gestational IGT and gestational diabetes.

Table 3 Other specific types of diabetes

| Genetic defects of β-cell function | Genetic defects in insulin action | e.g. Lipoatrophic diabetes |
| Diseases of the exocrine pancreas | e.g. Pancreatitis, Trauma/pancreatectomy, Neoplasia, Cystic fibrosis |
| Endocrinopathies | e.g. Cushing’s syndrome, Acromegaly, Phaeochromocytoma, Hyperthyroidism |
| Drug- or chemical-induced | e.g. cortisone, anti-depressant drugs, BBs, thiazide |
| Infections | e.g. Cytomegalovirus |
| Uncommon forms of immune-mediated diabetes |

Figure 2 Disorders of glycaemia: aetiological types and clinical stages (see also Table 3).
hepatic glucose output. Abnormalities of these functions characterize IFG. During an OGTT, the normal response to the absorption of the glucose load is both to suppress hepatic glucose output and to enhance hepatic and skeletal muscle glucose uptake. To keep a post-load glucose level within the normal range requires appropriate dynamics of the β-cell secretory response, amount and timing, in combination with adequate hepatic and muscular insulin sensitivity.

**Recommendation**

The definition and diagnostic classification of diabetes and its pre-states should be based on the level of the subsequent risk of cardiovascular complications. Class I, Level of Evidence B.

**Glycated haemoglobin**

Glycated haemoglobin (HbA1c), a useful measure of metabolic control and the efficacy of glucose-lowering treatment, is an integrated summary of circadian blood glucose during the preceding 6–8 weeks, equivalent to the lifespan of erythrocytes. It provides a mean value but does not reveal any information on the extent and frequency of blood glucose excursions. HbA1c has never been recommended as a diagnostic test for diabetes. A primary reason is the lack of a standardized analytical method and therefore lack of a uniform, non-diabetic reference level between various laboratories. A high HbA1c may only identify a fraction of asymptomatic people with diabetes. HbA1c is insensitive in the low range and a normal HbA1c cannot exclude the presence of diabetes or IGT.

**Markers of glucometabolic perturbations**

An inherent difficulty in the diagnosis of diabetes is the present lack of an identified, unique biological marker that would separate people with IFG, IGT, or diabetes from people with normal glucose metabolism. The use of diabetic retinopathy has been discussed, but the obvious limitation is that this condition in a majority of the patients only becomes evident after several years of hyperglycaemic exposure. On the other hand, diabetic retinopathy is diagnosed in ~1% of the non-diabetic population. Thus far, total mortality and CVD have not been considered for defining those glucose categories that carry a significant risk. Nevertheless, the vast majority of people with diabetes die from CVD and asymptomatic glucometabolic perturbations more than double mortality and the risk for myocardial infarction (MI) and stroke. Since the majority of type 2 diabetic patients develop CVD, which is a more severe (often even fatal) and costly complication of diabetes than retinopathy, CVD should be considered when defining cut-points for glucose.

**Comparisons between FPG and 2-hPG**

The diagnostic levels of FPG and 2-hPG are largely based on their association with the risk of having or to develop retinopathy. As outlined in the 1997 report by the ADA, the incidence of retinopathy increases already above a FPG of ≥7.0 mmol/L, and not above the higher threshold level of 7.8 mmol/L as previously used for the diagnosis of diabetes. The DECODE Study (Figure 3) has shown that any mortality risk in people with elevated FPG is actually related to a concomitantly elevated 2-hPG glucose. Thus, the current cut-off point for diabetes based on a 2-hPG ≥11.1 mmol/L may be too high. Lowering the threshold, although not yet formally challenged.

It has been noted that, although an FPG ≥7.0 mmol/L and a 2-hPG of ≥11.1 mmol/L sometimes identifies the same individuals, often they may not coincide. In the DECODE Study, recruiting patients with diabetes by either criterion alone or by their combination, only 28% met both, and 40% met the fasting and 31% the 2-hPG criterion only (Figure 4). Among those who met the 2-hPG criterion, 52% did not meet the fasting criterion, and 59% of those who met the fasting criterion did not meet the 2-hPG criterion. In the U.S. NHANES III Study of previously undiagnosed diabetic adults aged 40–74 years, 44% met both the FPG and the 2-hPG criteria, whereas 14% met the FPG criterion only and 41% the 2-hPG criterion only.

**Screening for undiagnosed diabetes**

Recent estimates suggest that 195 million people throughout the world have diabetes and that this number will increase to 330, maybe even to 500 million, by 2030. Many patients, up to 50% in most investigations, with type 2 diabetes are undiagnosed since they remain asymptomatic and therefore are undetected for many years. Detecting people with undiagnosed type 2 diabetes is important for both public health and every clinical practice. Mass screening for asymptomatic diabetes has not been recommended in the general population pending evidence that the prognosis of such patients will improve by early detection and treatment. Importantly, lack of evidence relates to lack of studies testing the hypothesis that early screening would indeed be advantageous. One such study (ADDITION) is ongoing in Denmark, the Netherlands, and the UK. Indirect evidence suggests that screening might be beneficial as it improves the possibility of early detection of diabetes and thereby improved prevention of cardiovascular complications. In addition, there is an increasing interest in identifying people with IGT, who might benefit from lifestyle or pharmacological intervention to reduce or delay the progression to diabetes.

Extensive data from epidemiological studies have challenged the practice not to utilize the 2-hPG showing that a substantial number of people, who do not meet the FPG criteria for abnormal glucose tolerance, will satisfy the criteria when exposed to an OGTT. Thus, the risk of a false negative diagnosis is substantial when measuring FPG alone. The argument for FPG over 2-hPG is primarily related to the matter of feasibility. An OGTT has been considered a less
well-suited tool at a population level, mainly because the test takes somewhat more than 2 h to conduct. However, 2-hPG is the only way to detect IGT. Many subjects with IGT will develop CVD before progressing to diabetes.\(^\text{28}\)

**Recommendation**

Early stages of hyperglycaemia and asymptomatic type 2 diabetes are best diagnosed by an OGTT that gives both fasting and 2-hPG values. Class I, Level of Evidence B.

**Detection of people at high-risk for diabetes**

Persons at high-risk for developing diabetes and those with asymptomatic diabetes by definition have no symptoms of diabetes and typically are not aware of their high-risk status. Although much attention has been directed at detecting undiagnosed type 2 diabetes in the past decades, only recently attention has turned to those with lesser degrees of glucometabolic abnormalities, which tend to share the same risk factors with type 2 diabetes.

Three general approaches for early detection exist: (i) measuring blood glucose to explicitly determine prevalent impaired glucose homeostasis (IGH), a strategy that will detect undiagnosed diabetes as well; (ii) using demographic and clinical characteristics and previous laboratory tests to determine the likelihood of future incident diabetes, a strategy that leaves current glycaemic state ambiguous; (iii) collecting questionnaire-based information on factors that provide information about the presence and extent of a number of aetiological factors for type 2 diabetes, a strategy that also leaves the current glycaemic state ambiguous.

The two latter approaches can serve as primary and cost-efficient screening tools, identifying a subgroup of the population in whom glycaemic testing may be targeted with a particular yield. The second option is particularly suited for certain groups, including those with pre-existing CVD and women who have had gestational diabetes, whereas the third option is better suited for the general population (Figure 5). Glycaemic testing is necessary as a secondary step in all three approaches to accurately define IGH, as the initial screening step is not diagnostic.

There will be a trade-off between sensitivity and specificity among the strategies. The final choice will depend on the goal and on relative health liabilities such as false positive vs. false negative. If the burden, as imposed by confirmatory testing, is not great and treatment is relatively harmless and inexpensive, one may accept a higher false positive rate. On the other hand, if the consequences of not treating in a timely manner are minor, a higher false negative rate may be acceptable. In algorithms that use multiple tests, the sequence will depend on the various steps leading to the confirmatory test, including costs, feasibility, and compliance. False labelling may be a problem in the first approach only, as the two other deals with elevated risk factors that are less sensitive to misclassification and by their own right already should lead to lifestyle advice.\(^\text{25}\) Including more glycaemic tests will contribute with more explicit information on the glycaemic status, whereas fewer tests result in more uncertainty. If a strategy does not incorporate an OGTT at any stage, individual glucose tolerance cannot be determined. Fasting glucose and HbA\(_1c\) will not reveal information about glucose excursions after meals or a glucose load.

It is necessary to separate three different scenarios: (i) general population; (ii) subjects with assumed metabolic abnormalities, including those who are obese, hypertensive, or who have a family history of diabetes; and (iii) patients with prevalent CVD. When patients with prevalent CVD have glucometabolic abnormalities, in most cases it is the 2-hPG value which is elevated, whereas fasting glucose is often normal.\(^\text{30}\) Thus, the measurement of fasting glucose alone should be avoided in such patients. Since patients with CVD by definition can be considered at high-risk, there is no need to carry out a separate diabetes risk assessment, but an OGTT should be carried out in them. In the general population, the appropriate strategy is to start with risk assessment as the primary screening tool combined with subsequent glucose testing of individuals identified to be at a high risk.\(^\text{31}\) This tool predicts the 10-year risk of type 2 diabetes with 85% accuracy, and in addition it detects current asymptomatic diabetes and abnormal glucose tolerance.\(^\text{32,33}\)

**Recommendation**

Primary screening for the potential type 2 diabetes can be done most efficiently using a non-invasive risk score, subsequently combined with a diagnostic oral glucose tolerance testing in people with high score values. Class I, Level of Evidence A.

Introduction

The prevalence of type 2 diabetes increases with age especially in Europe. Post-load hyperglycaemia reflects the acute increase in blood glucose after a glucose load, whereas fasting blood glucose shows the glucose concentration after an overnight fast and reflects mostly hepatic glucose production. They represent physiologically different aspects of glucose metabolism and may be differently influenced by the ageing process; post-prandial glucose excursions increase with age. The impact of gender on different abnormalities in glucose regulation is another unsolved issue. Recently, the DECODE Study reported data on the age- and gender-specific prevalence of diabetes and IGH, as well as the age- and gender-specific prevalence of isolated fasting or 2-h post-load hyperglycaemia in European populations.

Prevalence of diabetes and IGH

Plasma glucose concentrations, age and gender

The mean 2-h plasma glucose concentration rises with age in European populations, particularly after the age of 50. Women have significantly higher mean 2-h plasma glucose concentrations than men, and this gender difference becomes more pronounced after the age of 70, probably because of survival disadvantage in men compared with women. Mean FPG concentration increases only slightly with age, in men up to 69 years and in women across all ages. Mean FPG concentration is higher in men than in women during the age period 30–69 years and becomes higher in women after 70 years.

Prevalence of diabetes and IGH

The age-specific prevalence of diabetes rises with age up to the seventh and eighth decades in both men and women. The prevalence is less than 10% in subjects below the age of 60, 10–20% between 60–69 years, whereas 15–20% in the oldest age groups have previously known diabetes and a similar proportion have screen-detected asymptomatic diabetes. This suggests that the lifetime risk of diabetes in European people is 30–40%.

The prevalence of IGT increases linearly by age, but the prevalence of impaired fasting glycaemia does not. In middle-aged people, the prevalence of IGH is about 15%, whereas in the elderly 35–40% of European people have IGH. The prevalence of diabetes and IGT defined by isolated post-load hyperglycaemia is higher in women than in men, but the prevalence of diabetes and impaired fasting glucose (IFG) diagnosed by isolated fasting hyperglycaemia is higher in men than in women.

Diabetes and coronary artery disease

The most common cause of death in European adults with diabetes is coronary artery disease (CAD). Several studies have demonstrated they have a risk that is two to three times higher than that among people without diabetes. There are wide differences in the prevalence of CAD in patients with type 1 or 2 diabetes and also between different populations. The follow-up study of 10 centres of the WHO Multinational Study of Vascular disease in diabetes, including about 4700 type 1 and 2 patients, revealed that Japanese patients had a notably lower incidence of CAD than subjects from other parts of the world. Furthermore, their CAD incidence rates were lower than those in many
compared to only 2–3% in similar patients without nephropathy. In this context, besides hyperglycaemia, other CVD risk factors, such as hypertension, smoking, and dyslipidaemia, seem to be important contributing factors for CAD.

Several studies compared the magnitude of risk for CAD associated with the history of type 2 diabetes or the presence of previous CAD. In a 7-year follow-up of a Finnish Study and a 20-year follow-up of the Nurse’s Health Study patients with type 2 diabetes without any previous acute coronary events had a similarly high number of fatal CAD events as non-diabetic patients with a previous MI. The combination of type 2 diabetes and previous CAD identifies a group of patients with particularly high risk for coronary deaths. Moreover, the Nurse’s Health Study indicated a strong relation between the duration of known diabetes and CAD mortality. Recently, data were reported from 51735 Finnish men and women, aged 25–74 years and followed for an average of 17 years, during which time 9201 deaths occurred. Among men with diabetes only, with MI only and with both diseases, combined hazard ratios (HR) for coronary mortality, adjusted for other risk factors, were 2.1, 4.0, and 6.4, respectively, compared to men without either disease. The corresponding HRs for women were 4.9, 2.5, and 9.4. HRs for total mortality were 1.8, 2.3, and 3.7 in men and 3.2, 1.7, and 4.4 in women. Diabetic men and women had comparable mortality rates, whereas coronary mortality among men was markedly higher. Thus, a history of diabetes and MI markedly increased CVD and all-cause mortality. The relative effect of diabetes was larger in women, whereas the relative effect of the history of MI was more substantial among men. The increased risk of CAD in subjects with diabetes was only partly explained by concomitant risk factors including hypertension, obesity, dyslipidaemia, and smoking. Thus, the diabetic state or hyperglycaemia itself and its consequences are very important for the increased risk for CAD and related mortality. Further support to the important relation between diabetes and MI was obtained from the Interheart Case Control Study. Diabetes increased the risk by more than two times in men and women independent of ethnicity.

Asymptomatic hyperglycaemia and CAD

In 1979, a series of papers from the International Collaborative Group did not find any consistent evidence for either a threshold or a graded association between asymptomatic hyperglycaemia and CAD. There were, however, several methodological concerns with these early studies. Many of them used fasting glucose only; moreover, differences in glucose assays, glucose load, sample time after loading, follow-up time, and the population studied may have contributed to the inconsistent observations. After the introduction of standard criteria, in 1980, several studies revealed an association between 2-h plasma glucose and CAD in the general population. Some studies also showed an association with fasting glucose. A meta-analysis of 20 epidemiological studies found a progressive relationship between plasma glucose, fasting and post-load, and the incidence of cardiovascular events among people without diabetes. However, the results were not adjusted for other potential confounding factors.

non-diabetic western populations. CVD was the most common cause of mortality accounting for 44% of all deaths among patients with type 1 and 52% in patients with type 2 diabetes. In the EURODIAB IDDM Complication Study, involving 3250 type 1 diabetic patients from 16 European countries, the prevalence of CVD (a past history and electrocardiographic abnormality) was 9% in men and 10% in women. The prevalence increased by age, from 6% in the age group 15–29 years to 25% in the age group 45–59 years, and with the duration of diabetes. In type 1 diabetic patients, the risk of CAD increases dramatically with the onset of diabetic nephropathy. Up to 29% of patients with childhood-onset type 1 diabetes and nephropathy will, after 20 years with diabetes, have CAD

Figure 7 Age- and gender-specific prevalence of diabetes in 13 European population-based cohorts included in the DECODE Study. DM1, diabetes determined by FPG ≥7.0 mmol/L and 2-h plasma glucose <11.1 mmol/L; DMP, diabetes determined by 2-h plasma glucose ≥11.1 mmol/L and FPG <7.0 mmol/L; DM1 and DMP, diabetes determined by FPG ≥7.0 mmol/L and 2-h plasma glucose ≥11.1 mmol/L; known diabetes, previously diagnosed diabetes. **P < 0.01; ***P < 0.001, for the difference in prevalence between men and women.

Figure 8 Age- and gender-specific prevalence of IGR in 13 European population-based cohorts included in the DECODE Study. Isolated-IGT, 2-h plasma glucose <7.8 mmol/L; FPG <6.1 mmol/L; isolated-IGT, 2-h plasma glucose of 7.8–11.0 mmol/L and FPG <6.1 mmol/L; IFG and IGT, FPG of 6.1–6.9 mmol/L and 2-h plasma glucose of 7.8–11.0 mmol/L. \(*P < 0.05; **P < 0.01; ***P < 0.001, for the difference in prevalence between men and women.

DMP, diabetes determined by 2-h plasma glucose ≥11.1 mmol/L and FPG <7.0 mmol/L; DM1 and DMP, diabetes determined by FPG ≥7.0 mmol/L and 2-h plasma glucose ≥11.1 mmol/L; known diabetes, previously diagnosed diabetes. **P < 0.01; ***P < 0.001, for the difference in prevalence between men and women.

asymptomatic hyperglycaemia and CAD. There were, however, several methodological concerns with these early studies. Many of them used fasting glucose only; moreover, differences in glucose assays, glucose load, sample time after loading, follow-up time, and the population studied may have contributed to the inconsistent observations. After the introduction of standard criteria, in 1980, several studies revealed an association between 2-h plasma glucose and CAD in the general population. Some studies also showed an association with fasting glucose. A meta-analysis of 20 epidemiological studies found a progressive relationship between plasma glucose, fasting and post-load, and the incidence of cardiovascular events among people without diabetes. However, the results were not adjusted for other potential confounding factors.
Recommendation
The relationship between hyperglycaemia and CVD is to be seen as a continuum. For each 1% increase of HbA1c, there is a defined increased risk for CVD. Class I, Level of Evidence A.

The risk of CVD for people with overt diabetes is increased by two to three times for men and three to five times for women compared to people without diabetes. Class I, Level A.

IGH and CAD
Cardiovascular risk and post-prandial hyperglycaemia
The major disagreement in the classification of glucose homeostasis between the criteria issued by WHO and ADA focuses on whether diabetes should be diagnosed by means of a fasting or a 2-hPG. While different people are identified as diabetic and particularly as having IGH, when testing for fasting glucose than for a post-load glucose, it is clinically important to know how these two entities relate to mortality and the risk for CVD. Three early cohort studies, the Whitehall Study, the Paris Prospective Study, and the Helsinki Policemen Study, assessed the relationship between 2-hPG and the risk for CAD in European men. With known diabetes excluded, CVD mortality in individuals with a high 2-hPG (>95th centile in the Whitehall Study and >80th centile in the Paris and Helsinki studies) was twice that in subjects with normal glucose levels. In the Japanese Funagata Diabetes Study, survival analysis concluded that IGT, but not IFG was a risk factor for CVD. In a recent Finnish Study, IGT at baseline was an independent risk predictor of incident CVD and premature all-cause and cardiovascular mortality, a finding not confounded by the development of clinically diagnosed diabetes during follow-up.

The 23-year follow-up of the Honolulu Heart Programme suggested a dose–response relationship between 1 h glucose after a 50 g load and CAD mortality. The Chicago Heart Study of ~12,000 men without a history of diabetes showed that white men with asymptomatic hyperglycaemia [1 h glucose ≥11.1 mmol/L (200 mg/dL)] had an increased risk of CVD mortality compared with men having a low post-load glucose <8.9 mmol/L (160 mg/dL). The Rancho Bernardo Study indicated that elderly Californian women (but not men) with isolated post-challenge hyperglycaemia [2-hPG ≥11.1 mmol/L (200 mg/dL) and FPG <7.0 mmol/L (126 mg/dL)] had a significantly increased risk of CVD.

Several studies assessed the association of CVD with fasting and 2-hPG. Based on longitudinal studies in Mauritius, Fiji, and Nauru, Shaw et al. reported that people with isolated post-challenge hyperglycaemia doubled their CVD mortality compared with non-diabetic persons, whereas there was no significant increase in mortality related to isolated fasting hyperglycaemia [FPG ≥7.0 mmol/L (126 mg/dL) and 2-hPG <11.1 mmol/L (200 mg/dL)]. In the Cardiovascular Health Study, including 4515 subjects above the age of 65 years, the relative risk for incident CAD was higher in individuals with abnormal glucose homeostasis (comprising IGT, IFG, and newly diagnosed diabetes, detected by both fasting and 2-hPG) than in those with normal glucose levels. However, criteria based on FPG alone were less sensitive than the WHO 1999 criteria based on fasting and 2-hPG for predicting CAD.

A recent analysis of the US Second National Health and Nutrition Survey data, including 3092 adults aged 30–74 years, found a graded increase in mortality associated with abnormal glucose tolerance ranging from a 40% greater risk in adults with IGT to an 80% greater risk in adults with newly diagnosed diabetes. The most convincing evidence for a relation between abnormal glucose tolerance and an increased CAD risk has been provided by the DECODE Study, jointly analysing data from more than 10 prospective European cohort studies including more than 22,000 subjects. Death rates from all-causes, CVD, and CAD were higher in diabetic subjects diagnosed by 2-hPG than in those not meeting this criterion. Significantly increased mortality was also observed in subjects with IGT, whereas there was no difference in mortality between subjects with impaired and normal fasting glucose. Multivariate analyses showed that high 2-hPG predicted mortality from all-causes, CVD, and CAD, after adjustment for other major cardiovascular risk factors, but high fasting glucose alone did not. High 2-hPG was a predictor for death, independent of FPG, whereas increased mortality in people with elevated FPG largely related to the simultaneous elevation of 2-hPG. On the other hand, FPG did not add any predictive information once 2-hPG was entered into the model. All-cause and CVD mortality were increased in subjects with an FPG ≥7.0 mmol/L (126 mg/dL), but even among them it was a simultaneous elevation of 2-hPG that explained the increased mortality. The largest absolute number of excess CVD mortality was observed in subjects with IGT, especially those with normal FPG. The relation of 2-hPG with mortality was linear, but such a relation was not seen with FPG.

Recommendation
Information on post-prandial (post-load) glucose provides better information about the future risk for CVD than fasting glucose, and elevated post-prandial glucose also predicts the cardiovascular risk in subjects with normal fasting glucose levels. Class I, Level of Evidence A.

Glycaemic control and cardiovascular risk
Although several prospective studies have unequivocally confirmed that post-load hyperglycaemia increases CVD morbidity and mortality and is a better predictor for subsequent events than a high FPG, it still remains to be demonstrated that lowering a high 2-hPG will reduce this risk in well designed, randomized controlled trials (RCT). Such studies are underway, but thus far data are scarce. A secondary endpoint analysis of the STOP-NIDDM (Study TO Prevent Non-Insulin-Dependent Diabetes Mellitus) revealed statistically significant reductions in CVD event rates in IGT subjects receiving acarbose compared with placebo. Since acarbose specifically reduces post-prandial glucose excursions, this is the first demonstration that lowering post-prandial glucose may lead to a reduction in CVD events. It should, however, be noted that the power in this analysis is low due a very small number of events.

The largest trial in type 2 diabetic patients so far, the United Kingdom Prospective Diabetes Study, was not powered to test the hypothesis that lowering blood glucose by intensive treatment can reduce the risk of MI, although there was a 16% (marginally significant) reduction in intensively compared with conventionally treated
patients. In this study, post-load glucose excursions were not measured and over the 10 years of follow-up, the difference in the HbA1c concentrations between the intensive and conventional groups was only 0.9% (7.0 vs. 7.9%). Moreover, the drugs used for intensive treatment, sulphonylureas, long-acting insulin and metformin, mainly influence FPG, but not post-prandial glucose excursions. The German Diabetes Intervention Study, recruiting newly diagnosed type 2 diabetic patients, is far the only intervention study that has demonstrated that controlling post-prandial hyperglycaemia (blood glucose measured 1 h after breakfast) had a greater impact on CVD and all-cause mortality than controlling fasting blood glucose.72 During the 11-year follow-up, poor control of fasting glycaemia did not significantly increase the risk of MI or mortality, whereas poor vs. good control of post-prandial glucose was associated with a significantly higher mortality. Additional support is obtained from a meta-analysis of seven long-term studies using acarbose in type 2 diabetic patients. The risk for MI was significantly lower in patients receiving acarbose compared with those on placebo.73

**Recommendation**

Improved control of post-prandial glycaemia may lower cardiovascular risk and mortality. Class IIb, Level of Evidence C.

**Gender difference in CAD related to diabetes**

In the middle-aged general population, men have a two to five times higher risk for CAD than women.74,75 The Framingham Study was the first to underline that women with diabetes seem to lose their relative protection against CAD compared with men.76 The reason for the higher relative risk of CAD in diabetic women than diabetic men is still unclear.

The 14-year follow-up of the Rancho Bernardo Study showed that the multivariate-adjusted relative hazards of death from CAD in diabetic, compared with non-diabetic subjects, was 3.3 in women and 1.9 in men.77 In a 13-year follow-up study of a Finnish cohort, free from CVD at baseline and with or without type 2 diabetes, the diabetes-related adjusted HR for a major coronary event was 2.8 (95%CI 2.0–3.7) for men and 9.5 (95%CI 5.5–16.9) for women.78 In a Scottish 12-year long follow-up, asymptomatic hyperglycaemia (casual blood glucose >7.0 mmol/L) was a significant risk factor for CVD in both genders, however, it was a stronger risk factor in women than in men.79 A review about the impact of gender on the occurrence of CAD mortality reported that the overall relative risk (the ratio of men to women) for CAD mortality was 1.46 (95%CI 1.21–1.95) in diabetic and 2.29 (2.05–2.55) in non-diabetic subjects. This suggests that the gender differential is reduced in diabetes.35 The result from the DECODE Study, including 8172 men and 9407 women without known diabetes, showed that newly diagnosed diabetic women had a higher relative risk for cardiovascular mortality than newly diagnosed diabetic men.68 This association was independent of age, body mass index (BMI), systolic blood pressure, total cholesterol, and smoking. Recent data related to hormonal replacement therapy show that, particularly in diabetic women, the risk of CVD increases significantly.80

A meta-analysis of 37 prospective cohort studies, including 447 064 diabetic patients estimated the diabetes-associated, gender-related risk of fatal CAD.81 CAD mortality was higher in patients with diabetes than in those without (5.4% vs. 1.6%). The overall relative risk among people with and without diabetes was significantly greater among women with diabetes 3.50 (95%CI 2.70–4.53) than among men with diabetes 2.06 (95%CI 1.81–2.34).

**Recommendation**

Glucometabolic perturbations carry a particularly high risk for cardiovascular morbidity and mortality in women, who in this respect need special medical attention. Class IIa, Level of Evidence B.

**Glucose homeostasis and cerebrovascular disease**

**Diabetes and stroke**

The risk for cerebrovascular morbidity and mortality (stroke, cerebrovascular accidents), which causes substantial costs for society, is magnified by diabetes.52–80 Indeed, CVD is the predominant long-term cause of morbidity and mortality in patients with both type 1 and type 2 diabetes. Since the first observations, presented by the Framingham investigators, several large population-based studies have verified an increased frequency of stroke in the diabetic population.85,88 Diabetes was the strongest single risk factor for stroke (relative risk for men 3.4 and for women 4.9) in a prospective study from Finland with a follow-up of 15 years.82 Diabetes is a prominent risk factor for ischaemic stroke, but data on haemorrhagic stroke have been controversial,90–92 although a recent report from the Framingham Study suggested an increased risk of haemorrhagic stroke in type 2 diabetes.88

In Europe, ischaemic CVD accounts for about 80% of all strokes,94 but the female: male mortality ratio differs for stroke subtypes, ethnicity, and age.93,94 DM also may cause microatheromas in small vessels, such as the lenticulostriate arteries, leading to lacunar stroke, one of the most common subtypes of ischaemic stroke. Lacunar stroke is a unique subtype and requires specific clinical and imaging features for diagnosis. The presence of DM was associated with symptomatic cerebral infarcts, but not with silent infarcts,95 which are five times as prevalent as symptomatic brain infarcts in the general population.96

An inverse correlation has been reported between diabetes and aneurysmal subarachnoid haemorrhage, but two studies claim that diabetes is closely associated with subarachnoid haemorrhage.97,98 Stroke patients with diabetes, or with hyperglycaemia in the acute stage of stroke, have a higher mortality, worse neurological outcome, and more severe disability than those without.82,90–101

There is much less information concerning the risk of stroke in type 1 than in type 2 diabetes. Deckert et al.102 who followed type 1 diabetic patients for more than 40 years, reported a 10% cumulative incidence of stroke and 7% mortality from stroke. The World Health Organization Multinational Study of Vascular Disease in Diabetes indicated increased cerebrovascular mortality in type 1 diabetic patients, however, with considerable variations between countries.103 Patients, generally, are much younger in type 1 than in type 2 diabetes, and stroke is known as a disease of elderly people with two-thirds of all strokes occurring above the age of 65 years. Thus, the true risk of stroke in type 1 diabetic patients may still be less well-established.
The data from the nationwide cohort of more than 5000 Finnish childhood-onset type 1 diabetic patients showed that, by the age of 50 years (i.e. after 20–40 years with diabetes), the risk for an acute stroke was equal to that of an acute coronary event without any gender-related difference. Presence of diabetic nephropathy was the strongest predictor of stroke, causing a 10-fold increase of risk.

**IGT and stroke**

Considerably less is known about the frequency of asymptomatic diabetes and IGT in patients with stroke. In a recent Austrian study involving 238 patients, 20% had previously known diabetes, 16% newly diagnosed diabetes, 23% IGT, but only 0.8% had IFG. Thus, as few as 20% had a normal glucose homeostasis. Another 20% of the patients had hyperglycaemic values, which could not be fully classified due to missing data in the OGTT. Patients with diabetes had more severe strokes at admission, a more serious outcome at discharge, and a higher rate of infectious complications. In an Italian study, 106 patients were recruited with acute ischaemic stroke and without any history of diabetes, 81 patients (84%) had abnormal glucose metabolism at discharge and 62 (66%) after 3 months (39% IGT and 27% newly detected diabetes). Post-load hyperglycaemia at discharge was a predictor of diabetes after 3 months.

**Recommendation**

People with diabetes and IGT have an increased risk for stroke. Class I, Level of Evidence A.

In stroke patients, unrecognized hyperglycaemia is mostly high post-load glucose seen in the OGTT, whereas the measurement of fasting glucose is insensitive in detecting unrecognized hyperglycaemia. Class I, Level of Evidence B.

**Prevention of CVD in people with IGH**

Although overall trends in CVD mortality have shown a significant downward trend in developed countries during the last decades, it has been suggested that the decline has been smaller or not existent at all in diabetic subjects. A more recent study reports on a 50% reduction in the rate of incident CVD events among adults with diabetes. The absolute risk of CVD was, however, two-fold greater than among persons without. More data are needed to judge this issue in European populations.

Accumulating evidence has shown that deterioration of IGT in type 2 diabetes can be effectively prevented by lifestyle intervention. Whether this also leads to the prevention of CVD needs to be seen in the follow-up of these trial populations.

An imminent issue is to prove that prevention and control of post-prandial hyperglycaemia will cause a reduction in mortality, CVD, and other late complications of type 2 diabetes. There is also a need to reconsider the thresholds used to diagnose hyperglycaemia. The majority of premature deaths related to IGH occur in people with IGT obviating the need for increased attention to people with a high 2-hPG. A first step would be to detect such people through systematic screening of high-risk groups (see the following section). The best way to prevent the negative health consequences of hyperglycaemia may be to prevent the development of type 2 diabetes. Controlled clinical outcome trials among asymptomatic subjects with hyperglycaemia are underway, but results will only be available after some years. Meanwhile, the only way to make clinical treatment decisions in such subjects is to make inferences from the observational epidemiological data and pathophysiological studies.

**The metabolic syndrome**

Longitudinal clinical and epidemiological studies consistently demonstrated that certain risk factors are important as causes of the mass occurrence of CVD in populations and also serve as contributing factors to increased risk at an individual level. These risk factors include dyslipidaemia, hyperglycaemia and diabetes, hypertension and factors linked to unhealthy life styles such as unhealthy eating habits, physical inactivity, overweight/abdominal obesity, and smoking. A family history of premature cardiovascular events, probably reflecting both genetic and environmental factors, has also been considered important in defining cardiovascular risk.
The clustering of metabolic and physiological abnormalities was noticed as early as 1923 by Kylin, who described a syndrome consisting of the co-existence of hypertension, hyperglycaemia, and hyperuricaemia. In 1947, Vague paid attention to the influence of body fat distribution on the development of metabolic abnormalities, but the real interest in clustering metabolic and physiological abnormalities started in the 1980s. In 1988, Reaven described a syndrome based on the clustering of the following abnormalities: resistance to insulin-stimulated glucose uptake, hyperinsulinaemia, hyperglycaemia, increased very low-density lipoprotein (VLDL) triglycerides, decreased high-density lipoprotein (HDL) cholesterol, and high blood pressure. Since then, there has been a growing interest in the clustering of factors, each one associated with increased risk for CVD. Subsequently, this syndrome became referred to as the ‘insulin-resistance syndrome’ or the ‘metabolic syndrome’. The role of obesity and its central distribution has become a subject of some debate. In his original description, Reaven considered that obesity did not belong to the syndrome, although it could contribute to its development. More recently, several new components have been proposed as belonging to the syndrome, including markers of inflammation, microalbuminuria, hyperuricaemia, and fibrinolytic and coagulation abnormalities.

Definitions

Currently, there are at least five definitions of the metabolic syndrome proposed by international or national organizations or expert groups: the World Health Organization (WHO) in 1998 revised in 1999; the European Group for Study of Insulin Resistance (EGIR) in 1999; the National Cholesterol Education Programme (NCEP) Adult Treatment Expert Panel III in 2001; the American Association of Clinical Endocrinologists (AACE) in 2003; and more recently International Diabetes Federation (IDF) Consensus Panel. The WHO and EGIR definitions were primarily proposed for research purposes and the NCEP and AACE definitions for clinical use. The 2005 IDF definition aims at worldwide clinical practice. Tables listing the various definitions are presented in the section on pathophysiology.

Studies on the relationship between the presence of metabolic syndrome and the risk of mortality and morbidity are still scarce, particularly, the comparison of risk by different definitions of the syndrome. Several studies in Europe revealed that the presence of the metabolic syndrome increased CVD and all-cause mortality, but a couple of reports from the US have shown inconsistent evidence. The Strong Heart Study followed up, for over 7.6 years, 2283 American Indians who were free of CVD and diabetes at baseline examination. The incidence of diabetes increased by the presence of the NCEP syndrome, but that of CVD did not. Age-and centre-adjusted HR for having the NCEP metabolic syndrome was 1.13 (95%CI 0.81–1.58) in non-diabetic participants. Based on the data of 2431 US adults aged 30–75 years participating in the second National Health and Nutrition Examination Survey (NHANES II), it was found that the metabolic syndrome was associated with a moderately increased risk of mortality from CVD, but not significantly associated with mortality from all-causes, CHD, or stroke. In the San Antonio Heart Study, after excluding subjects with diabetes, the corresponding relative risk for all-cause mortality decreased substantially from 1.45 (1.07–1.96) to 1.06 (0.71–1.58) for the NCEP definition and from 1.23 (0.90–1.66) to 0.81 (0.53–1.24) for a modified WHO syndrome. A recent study revealed that the NCEP metabolic syndrome is inferior to established predictive models for either type 2 diabetes or CVD. Lawlor et al. recently showed that point estimates of the effect for each definition of the syndrome were similar as or even weaker than those for individual factors, suggesting there is little additional prognostic value in defining the individual factors as a syndrome for predicting CVD mortality. Although each definition of the metabolic syndrome includes several risk factors they are defined dichotomously. Thus, such a prognostic formula cannot predict CVD as accurately as a risk model based on continuous variables.

Recommendation

The metabolic syndrome identifies people at a higher risk of CVD than that in the general population, although it may not provide a better or even equally good prediction of cardiovascular risk than scores based on the major cardiovascular risk factors (age, blood pressure, smoking, and serum cholesterol). Class II, Level of Evidence B.

Risk charts

Various risk charts or scores have been developed to assess the risk for non-fatal or fatal cardiovascular events within a given time frame in individuals without a previous cardiovascular diagnosis. The first of these, the Framingham risk score, has been available since 1967 in the US, comprising the major risk factors known by that time: gender, age, systolic blood pressure, total cholesterol, cigarette smoking, and diabetes. The most recent Framingham score added HDL-cholesterol and deleted left ventricular (LV) hypertrophy. The Framingham and other risk scores have been tested in different populations and the conclusion from the comparative studies is that, while the absolute risk may differ from population to population, the proportionate risk ranking provided by these scores is consistent across populations.

A European Heart Score has been generated based on pooled data from more than 200 000 men and women, which takes the overall CVD risk profile into account. It does, however, only include the traditional risk factors: age, gender, total cholesterol, smoking, and systolic blood pressure. This risk score is based on fatal events. Diabetes has not yet been taken into account as it was not uniformly defined in the cohorts based upon which this score was developed. Future attempts will be made to include diabetes and 2-hPG.

Recommendation

Several cardiovascular risk assessment tools exist and they can be applied to both non-diabetic and diabetic subjects. Class I, Level of Evidence A.

Diabetes is a major risk factor for CVD

In the EUROASPIRE II cohort, 29% of all coronary patients had known diabetes and another 23% IGT. The mortality follow-up of the EUROASPIRE I cohort showed that, apart from smoking, diabetes is the most important, single risk
factor for total and cardiovascular mortality in these coronary patients. Results from a number of cohort studies, particularly the large European DECODE Study, indicate that either fasting or 2-hPG are independent risk factors for all-cause and cardiovascular morbidity and mortality even in people without diagnosed diabetes. More recently, the DECODE group developed a CVD risk score, which presently is the only one of its kind including IGT or IFG in the risk function determination.

Risk functions are usually estimated quantitatively depending on the characteristics of the studied population and the risk factors that have been included. Each population may have a different distribution of risk factors, which may weigh differently in determining the disease and the disease may occur with different probability. Moreover, there must be secular differences between different generational cohorts within one population. Therefore, the predictive accuracy of a risk score may be only adequate for the index population. It is a challenge to know whether a worldwide uniform CVD risk assessment tool can be developed.

A population strategy for altering life style and environmental factors, the underlying causes of the mass occurrence of CAD, has been considered since 1982 in a report of the WHO Expert Committee on Prevention of Coronary Heart Disease. This is in accordance with the notion that even small decreases in the risk factor pattern at a population level, through the large number of individuals involved, will affect the health of many people. Such an approach has proven successful in Finland. There is now a need to develop a CVD risk assessment tool based on easily available information and intended for public health purposes similar to the one developed to predict the development of type 2 diabetes in Finland. This Finnish Diabetes Risk Score (FINDRISC) (see the section on Detection of people at high-risk for diabetes; Figure 5) predicts the 10-year risk for developing type 2 diabetes with 85% accuracy. It also detects asymptomatic diabetes and abnormal glucose tolerance with high reliability in other populations. In addition to the prediction of diabetes, FINDRISC predicts the incidence of MI and stroke. Such high-risk individuals identified by a simple scoring system can be a target for proper management, not only for diabetes prevention, but at the same time, for CVD prevention.

Recently, the definition of the NCEP metabolic syndrome and the Framingham cardiovascular risk score were compared for the prediction of cardiovascular events. Data from the population-based San Antonio Study showed that the Framingham risk score predicted CVD better than the metabolic syndrome. This is not surprising considering that the Framingham score, in contrast to the metabolic syndrome, was specifically developed to predict cardiovascular events and that it differs by including smoking as a risk factor. In the Atherosclerosis Risk in Communities Study ARIC cohort, the metabolic syndrome was found to be predictive of cardiovascular events, both in men and women, but as in the San Antonio Study, the inclusion of the metabolic syndrome did not improve the coronary risk prediction beyond what was achieved with the Framingham risk score. Nevertheless, neither the definition of the metabolic syndrome nor any of the CVD risk scores are perfect with regard to the accuracy of risk prediction.

Recommendation
An assessment of predicted type 2 diabetes risk should be part of the routine health care using the risk assessment tools available. Class II, Level of Evidence A.

Patients without known diabetes but with established CVD should be investigated with an OGTT. Class I, Level of Evidence B.

Preventing progression to diabetes
The development of type 2 diabetes is often preceded by a variety of altered metabolic states, including IGT, dyslipidaemia, and insulin resistance. Although not all patients with such metabolic abnormalities progress to diabetes, their risk of developing the disease is significantly enhanced. Life style factors, such as poor diet and a sedentary life style, which in turn lead to obesity, have a major impact on the risk of developing type 2 diabetes. Carefully conducted clinical studies have demonstrated that effective life style intervention strategies and drug treatments can prevent or at least delay the progression to type 2 diabetes in high-risk individuals.

The Swedish Malmö Study used increased physical exercise and weight loss as major intervention strategies to prevent or delay type 2 diabetes. Subjects with IGT had less than half the risk of developing type 2 diabetes compared with those who did not take part in the exercise programme during 5 years of follow-up.

In a Chinese study from Da Qing, 577 individuals with IGT were randomized by clinic into one of the four groups: exercise only, diet only, diet plus exercise, and a control group. The cumulative incidence of type 2 diabetes during 6 years was significantly lower in the three intervention groups compared with the control group (41% in the exercise group, 44% in the diet group, 46% in the diet plus exercise group, and 68% in the control group) and this difference remained significant after adjusting for differences in baseline BMI and fasting glucose.

The Finnish Diabetes Prevention Study found that a reduction in bodyweight achieved through an intensive diet and exercise programme was associated with a 58% reduction in the risk of developing type 2 diabetes ($P < 0.001$). Middle-aged men ($n = 172$) and women ($n = 350$) who were overweight and had IGT were randomized to the intervention group or to a control group who had conventional care. The goals of the life style interventions were to achieve a $5\%$ reduction in bodyweight, reduce all fat intake to less than $10\%$ of energy consumption, particularly saturated fat less than $10\%$ of energy consumption, increase fibre intake of at least $15\,\text{g/1000\,kcal}$, and undertake a programme of moderate exercise for 30 min/day or more. After 2 years, patients in the intervention group had achieved a significantly greater mean reduction in body-weight compared with those in the control group ($P < 0.001$). They also demonstrated favourable changes in measures of glycaemia, including improved fasting and post-challenge plasma glucose levels. In addition, fewer subjects in the intervention group developed type 2 diabetes than in the control group [58% relative risk reduction (RRR); $P < 0.001$]. The reduction in the risk of progression to diabetes was directly related to the magnitude of the changes in life style; none of the patients who had achieved at least four of the intervention goals by 1 year developed type 2 diabetes during follow-up.
The U.S. Diabetes Prevention Programme also found that life style modification reduced the incidence of type 2 diabetes by 58% in overweight American adults with IGT. A total of 3234 adults (1043 men and 2191 women) were randomized to standard life style recommendations plus placebo or metformin 850 mg twice daily, or to an intensive life style modification programme. The goal of the programme was to achieve and maintain ≥7% reduction in body weight, through a low-calorie, low-fat diet plus physical activity of moderate intensity for at least 150 min per week. Patients in the life style intervention group had a significantly greater mean reduction in body weight (5.6 kg,  P < 0.001) compared with those in the placebo (0.1 kg) and metformin groups (2.1 kg). The cumulative incidence of diabetes during the follow-up period was lower in the life style intervention and metformin groups than in the placebo group, with incidence rates of 4.8, 7.8, and 11.0 cases per 100 person-years, respectively. This reduction in incidence equated to one case of diabetes prevented for every seven people with IGT treated for 3 years in the life style intervention group, compared with 14 of the metformin group.

The STOP-NIDDM Trial was a double-blind, placebo-controlled, randomized trial comprising 1429 subjects with IGT. The α-glucosidase inhibitor acarbose was used as an active agent in this trial with the primary aim to determine whether the incidence of diabetes could be prevented. The risk of progression to diabetes over 3.3 years was reduced by 25%. Furthermore, acarbose increased the probability of IGT reverting to normal glucose tolerance over time.

In light of the impressive results of the Finnish Diabetes Prevention Study and the Diabetes Prevention Programme, the ADA and the National Institutes of Diabetes, Digestive, and Kidney Diseases (NIDDK) recommend that people over 45 years with BMI ≥ 25 kg/m² should be screened for evidence of high blood glucose. People found to have evidence of a pre-diabetic state should be given appropriate counseling on the importance of weight loss through a programme of dietary modification and exercise. In addition, since patients with the metabolic syndrome have an increased risk of CVD and mortality, life style interventions in obese patients and those with obesity or hyperglycaemia are likely to be beneficial in terms of overall health and life expectancy. The numbers needed to treat (NNT) to prevent one case of type 2 diabetes with life style intervention in people with IGT is dramatically low. Thus, the benefits from the life style intervention are great. In the recently reported Indian Diabetes Prevention Programme (IDPP), life style and metformin showed similar capability to reduce the incidence of diabetes, but a combination of these two treatment possibilities did not improve the outcome.

The Diabetes REduction Assessment with ramipril and rosiglitazone Medication (DREAM) trial investigated prospectively whether these two pharmacological compounds may reduce the onset of diabetes, using a factorial design, in people with impaired glucose tolerance, impaired fasting glucose or both. The primary endpoint was the development of diabetes or death. After a median follow up time of three years, the incidence of this endpoint did not differ significantly between ramipril and placebo (18.1% vs. 19.5%; HR 0.91; 95% CI 0.81–1.03). Rosiglitazone reduced the endpoint significantly (n = 3306; 11.6%) compared with placebo (n = 686; 26.0%; HR 0.40; 0.35–0.46; P < 0.0001). Thus the effect of rosiglitazone on the likelihood to develop diabetes in people with impaired glucose homeostasis was as could be expected considering its known glucose lowering property. Overall, total cardiovascular events did not differ significantly between the rosiglitazone and placebo groups. In the rosiglitazone group, however, body weight increased significantly (P < 0.0001) and more heart failure cases (0.5 vs. 0.1%; P < 0.01) were found. The DREAM trial was neither planned nor powered to evaluate cardiovascular outcomes, which would have demanded a longer trial period. Also, a longer follow-up is needed to see whether the glucometabolic effect of rosiglitazone on glucose only lasts as long as the treatment is continued, or if it is sustained. Thus, rosiglitazone cannot, until further evidence has been gained, be considered appropriate management to reduce the risk of cardiovascular disease in people with impaired glucose homeostasis.

The recent data from the STOP-NIDDM Trial have for the first time suggested that acute cardiovascular events in people with IGT may be prevented by treatment that reduces post-prandial glucose levels. Furthermore, data based on NHANES III have shown that control of LDL-cholesterol, HDL-cholesterol, and blood pressure to normal levels in patients with the metabolic syndrome (without diabetes and CAD) would result in preventing 51% of coronary events in men and 43% in women; control of these risk factors to optimal levels would result in preventing 81% and 82% of events, respectively. The identification of high-risk subjects for type 2 diabetes is relatively easy; no biochemical or other costly tests are required. It is now recognized, that from a prevention point of view, screening for type 2 diabetes is not the same as measuring blood glucose, but one can determine the risk of developing type 2 diabetes using non-invasive data before testing for blood glucose. Diabetes risk scores have been developed in several populations. It is also important to note that most of

*Combined numbers for placebo and diet and exercise groups.
the high-risk subjects for type 2 diabetes are already regular customers of primary health care services for various reasons. What is needed in the health care system is to determine the future risk of type 2 diabetes using easy tools such as the FINDRISC in individuals that seem to be potential candidates of type 2 diabetes. The individuals with high scores should be systematically targeted with lifestyle intervention regardless of their current glucose levels. It is necessary that such an intervention will become a part of the routine preventive care in order to reduce the burden of type 2 diabetes.

**Recommendation**
People at high risk for type 2 diabetes, should receive appropriate lifestyle counselling and if needed, pharmacological therapy to reduce or delay their risk of developing diabetes. This may also decrease their risk of CVD. Class I, Level of Evidence A.

In people with IGT, the onset of diabetes can be delayed by certain drugs (such as metformin, acarbose and rosiglitazone). Class I, Level of Evidence A.

**Prevention of CVD by physical activity**
In previous years, several studies assessed the association between physical activity and the risk of cardiovascular mortality among diabetic patients. The results of these studies indicated that regular leisure-time physical activity is associated with reduced CVD and total mortality among patients with diabetes. Walking had a similar inverse association with the risk of cardiovascular and total mortality as vigorous leisure-time physical activity. Other types of physical activity, such as occupational and daily commuting physical activity on foot or by bicycle, have also been found to be associated with reduced cardiovascular mortality among diabetic patients; people physically active at their workplace had a 40% lower cardiovascular mortality compared with people with low physical activity at work. A high level of leisure-time physical activity was associated with a 33% drop in cardiovascular mortality and moderate activity was linked to a 17% drop in cardiovascular mortality compared to the most sedentary group. Daily walking or cycling to and from work decreased cardiovascular mortality, but this relation was no longer significant after additional adjustment for occupational and leisure-time physical activity. Simultaneously doing one, two, or three types of moderate or high occupational, commuting, and leisure-time physical activity reduced significantly total mortality, but this relation was no longer significant after additional adjustment for occupational and leisure-time physical activity. The ADA, the National Cholesterol Education Programme Expert Panel, and International Diabetes Federation (European Region) have recommended physical activity for the primary and secondary prevention of CVD complications among diabetic patients. The assessment of the level of physical activity is not difficult. It can be done using simple questionnaires, or using pedometers, or more sophisticated equipment. The most important thing is that it is done and that health workers motivate diabetic patients to be physically active.

**Recommendation**
Diabetic patients should be advised to be physically active in order to decrease their cardiovascular risk. Class I, Level of Evidence A.

**Pathophysiology**

**Role of hyperglycaemia**

Hyperglycaemia characterizes both type 1 and type 2 DM. Since a number of studies closely linked elevated blood glucose levels to excess mortality and morbidity from vascular disease, growing efforts currently focus on clarifying the effects of glucose on vascular function in particular endothelial function and nitric oxide (NO) bioavailability.

NO causes vasodilation and platelet inhibition and thereby prevents vasoconstriction and thrombus formation. NO is generated by a family of enzymes called NO synthase. One of these enzymes, i.e. endothelial NOS (eNOS), is \( \text{Ca}^{2+} \)-dependent and constitutively present in various types of cells, including endothelial cells. The activity of the \( \text{L-arginine/NO} \) pathway is a balance between synthesis and breakdown of NO by its reaction with the superoxide anion (\( \text{O}_2^- \)). Under physiological conditions, the production of this molecule is not markedly affected by \( \text{O}_2^- \). Hence, NO may exert its well-known vascular protective effects favouring an anti-atherosclerotic environment. However, in the presence of cardiovascular risk factors, an excessive production of \( \text{O}_2^- \) occurs rapidly inactivating NO and leading to the formation of high concentrations of peroxynitrite (\( \text{ONOO}^- \)), a very powerful oxidant (Figure 9).

Several lines of evidence support the concept that hyperglycaemia decreases endothelium-derived NO availability and affects vascular function via a number of mechanisms as depicted in Figure 10, mainly involving overproduction of reactive oxygen species (ROS), namely \( \text{O}_2^- \).

The mitochondrial electron transport chain is probably one of the first targets of high glucose, with a direct net increase in \( \text{O}_2^- \) formation. A further increase in \( \text{O}_2^- \) production is driven by a vicious circle involving ROS-induced activation of protein kinase C (PKC) and vice versa (Figure 11). Indeed, activation of PKC by glucose has implicated in the regulation and activation of membrane-associated NAD(P)H-dependent oxidase, this latter leading to subsequent production of superoxide anion. Indeed, NAD(P)H activity and subunit protein expression are enhanced in internal mammary arteries and

![Figure 9](image)

![Figure 10](image)

![Figure 11](image)
saphenous veins of diabetic patients. Moreover, high glucose-dependent PKC activation induces an upregulation of inducible COX-2 and eNOS expression as well as a selective increase of thromboxane production and reduced NO release. Hence, activation of the PKC pathway represents a proximal node in the intracellular signalling leading to hyperglycaemia-induced oxidative stress and endothelial dysfunction.

Oxygen-derived free radical excess affects endothelial function via a number of different pathways: (i) O2\textsuperscript{-} rapidly inactivates NO to peroxynitrite,\textsuperscript{209} a powerful oxidant which easily penetrates across phospholipid membranes and produces substrate nitration, thereby inactivating regulatory receptors and enzymes, such as free radical scavengers\textsuperscript{206,207} and key NOS co-factors, for instance tetrahydrobiopterin;\textsuperscript{208} (ii) mitochondrial production of superoxide increases intracellular formation of advanced glycation end-products (AGEs), which adversely affect endothelial function by increasing ROS production and inflammatory cytokines from vascular cells, thereby enhancing endothelial expression of various adhesion molecules implicated in atherogenesis;\textsuperscript{209} (iii) activation of the receptor for AGEs (RAGE) increases intracellular superoxide anion production\textsuperscript{210} and seems to represent a key step in atherosclerotic lesion development;\textsuperscript{211} (iv) O2\textsuperscript{-} production activates the hexosamine pathway, which lowers Akt-induced NOS activation.\textsuperscript{212} Akt activation is further limited by PKC-dependent inhibition of phosphatidylinositol-3 kinase pathway; (v) high glucose-induced oxidative stress increases the levels of dimethylarginine, a competitive antagonist of NOS.\textsuperscript{213}

The impact of DM on vascular function is not limited to the endothelium. In patients with type 2 DM, the vasodilator response to exogenous NO donors is diminished.\textsuperscript{214} Dysregulation of vascular smooth muscle function is further enhanced by impairments in sympathetic nervous system function. Diabetes increases protein kinase C (PKC) activity, NF-kB production, and generation of oxygen-derived free radicals in vascular smooth muscle, akin to these effects in endothelial cells. Moreover, diabetes heightens migration of vascular smooth muscle cells into nascent atherosclerotic lesions, where they replicate and produce extracellular matrix—important steps in mature lesion formation.\textsuperscript{215} Vascular smooth muscle cell apoptosis in atherosclerotic lesions is also increased, such that patients with diabetes tend to have fewer smooth muscle cells in the lesions, which increases the propensity for plaque rupture.\textsuperscript{216} In persons with diabetes, production of cytokines diminishes vascular smooth muscle synthesis of collagen and increases production of matrix metalloproteinases, resulting in an increased tendency for plaque destabilization and rupture.

Given the above effects of hyperglycaemia on vascular function, one might speculate that tight glycaemic control warrants preservation from micro- and macrovascular damage and that it favourably impacts prognosis in diabetic patients. Epidemiological studies support the notion that increasing blood glucose levels proportionally relates to
cardiovascular events. Less is known on the effect of very strict glycaemic control. In the United Kingdom Prospective Diabetes Study (UKPDS), 71 the risk of death, stroke, or amputation did not change while there was a trend towards less MIs in the most actively treated group. Glycaemic control was, however, rather modest with a glycated haemoglobin A1c (HbA1c) of 7% in the intervention group and only a small difference of 0.9% between the intervention and the control groups. Still, improved treatment of hyperglycaemia lowered the incidence of diabetic retinopathy and nephropathy.

Role of insulin resistance and β-cell dysfunction

Insulin resistance is a typical characteristic of type 2 diabetes. Insulin stimulates NO production from endothelial cells by increasing the activity of NOS via activation of phosphatidylinositol-3 kinase (PI-3K) and Akt kinase. Thus, in healthy subjects, insulin increases endothelium-dependent (NO-mediated) vasodilatation. On the contrary, endothelium-dependent vasodilatation is reduced in insulin-resistant subjects. Furthermore, insulin-mediated glucose disposal correlates inversely with the severity of the impairment in endothelium-dependent vasodilatation. Abnormal endothelium-dependent vasodilatation in insulin-resistant states may be explained by alterations in intracellular signalling that reduce the production of NO. Insulin signal transduction via the PI-3K pathway is impaired and insulin is less able to produce NO. On the other hand, insulin signal via the mitogen-activated protein kinase pathway (MAPK) remains intact. MAPK activation is associated with increased endothelin production and a greater level of inflammation and thrombosis. Insulin resistance is a distinct trait of DM, and its magnitude directly relates to cardiovascular outcomes. 217,218

Evidence has accumulated during the last decade on the significant roles of both decreased insulin sensitivity and β-cell dysfunction in the pathogenesis of type 2 DM. The relative importance and causal relations of these disturbances in the pathogenesis of diabetes are under debate. Both insulin secretion and insulin sensitivity are genetically and environmentally controlled and the impairment of both has individually or together been associated with increasing risk of developing type 2 DM. 219-221 It has been reported that during each stage of the development of type 2 DM, decreased insulin sensitivity and insulin secretory dysfunction are independent predictors of worsening glucose tolerance. 222 Indeed, fasting hyperinsulinaemia, known to reflect decreased insulin sensitivity, together with decreased insulin secretion are the strongest independent predictors of type 2 DM. 223 Furthermore, decreased β-cell function may exist already at normal FPG levels. 224 Several studies have presented results that indicate that β-cell dysfunction in early stages of abnormal glucose tolerance is independent of insulin resistance and already present in obese patients with normal glucose tolerance. 225-227 In addition, a study of type 2 diabetic Japanese patients recently showed that decreased insulin secretion had a more pronounced impact on glucose tolerance than insulin sensitivity. 228 Both glucose toxicity and lipotoxicity have been reported to contribute to β-cell dysfunction. The lipotoxicity has above all been associated with elevated plasma free fatty acids (FFA), which have been observed to hamper insulin secretion through toxic effects on the β-cells. 229,230 Furthermore, long-term lowering of plasma FFA concentrations improves the acute insulin response and insulin-mediated glucose uptake. 231 A recent study 232 has shown that glucose abnormalities in patients with acute MI (AMI), but without previously known type 2 DM to a significant extent are related to impaired β-cell secretion of insulin. This confirms that hyperglycaemia immediately after an infarction is not a stress-epiphénoménon but reflects stable disturbances of glucose regulation preceding the AMI. Early β-cell dysfunction may have important pathophysiological implications and may serve as a future treatment target.

Risk factors for atherosclerosis

Oxidative stress

Given the pivotal role of oxidative stress on endothelial function and atherosclerotic processes in diabetes, growing efforts focus on the putative effects of antioxidant therapy. Despite evidence indicating reversal of endothelial dysfunction by different antioxidant agents, 233 data from clinical trials are still inconclusive and presently it does not support an indication for antioxidant therapy in DM. 234,235 These data would seem to refute a role of oxidative stress in the pathogenesis of atherosclerosis. There are several reasons to believe that this conclusion is not justified but rather that treatment with antioxidants is perhaps not the best approach for reducing oxidant stress. First, the rate of the reaction between vitamin E and superoxide is several orders of magnitude less than the rate of the reaction of superoxide with NO. Secondly, many of the oxidative events occur in the cytoplasm and in the extracellular space, and would not be affected by lipid-soluble antioxidants that are concentrated in lipid membranes and lipoproteins. Thirdly, antioxidants may become pro-oxidants after scavenging a radical, vitamin E and C become tocopheroxyl and ascorbyl radicals, respectively. The tocopheroxyl radical can be regenerated by other antioxidants such as vitamin C or co-enzyme Q10. For this reason, the use of cocktails of antioxidants rather than high doses of a selected one may be more effective. Given the above considerations, it is quite possible that use of antioxidant vitamins will never prove to be the best approach to limit vascular oxidant stress. To prevent the development of the latest stages of diabetic vascular disease, future research should focus on identifying substances which have antioxidant effects not because they scavenge radicals, but because they block the production of radicals.

Lipid disorders

Classically, DM induces elevation in triglyceride and LDL, and decline in HDL plasma levels. These changes clearly affect the natural history of the atherosclerotic disease, and render patients with diabetes more prone to develop CAD, stroke, and peripheral vascular disease. Recent evidence confers to diabetes-related enhanced FFA liberation, a crucial role in producing the well-described changes in lipid profile. Excess circulating levels of FFA results from both enhanced release from adipose tissue and reduced uptake by skeletal muscle. 236 The liver responds to FFA excess by increasing VLDL production and cholesteryl ester synthesis. 237 The accumulation of triglyceride-rich
lipoproteins, depends also on their reduced clearance by lipoprotein lipase, triggers hypertriglyceridaemia and lowers HDL levels by promoting exchanges from HDL to VLDL via cholesteryl ester transfer protein. HDLs are not only reduced in quantity, but also impaired in function. Indeed, HDL from poorly controlled type 2 diabetic patients are less effective in preventing LDL oxidation compared to those from non-diabetic subjects. Moreover, increased VLDL production and abnormal cholesterol and triglyceride transfer between VLDL and LDL enhances plasma levels of small and dense proatherogenic LDLs, which are in addition more prone to oxidation due to impaired antioxidant defence mechanisms in the plasma of diabetics. The proatherosclerotic effects of these particles on coronary, carotid, and peripheral arteries, have important clinical consequences, thus representing an important treatment target.

Thrombosis and coagulation
Platelet function is crucial in determining the natural history of atherosclerosis and consequences of plaque rupture. It is therefore not surprising that cardiovascular risk is closely linked to platelet function abnormalities and coagulation disorders in the diabetic patient. The intracellular platelet glucose concentration mirrors the extracellular environment and is associated with increased superoxide anion formation, PKC activity, and decreased platelet-derived NO. Moreover, diabetic patients show increased expression of glycoprotein Ib and IIb/IIIa, which enhances both platelet–vWF factor and platelet–fibrin interaction. Hyperglycaemia further affects platelet function by impairing calcium homeostasis, and thereby altering platelet conformation, secretion and aggregation, and thromboxane formation. Further abnormalities affecting platelet function include impaired endothelial production of nitric oxide and prostacyclin, and increased production of fibrinogen, thrombin, and von Willebrand factor. Moreover, blood coagulability is enhanced in diabetic patients. Indeed, plasma coagulation factors (e.g. factor VII and thrombin), lesion-based coagulants (e.g. tissue factor), plasminogen activator inhibitor-1 (PAI-1) (a fibrinolysis inhibitor) are increased, and endogenous anticoagulants (e.g. thrombomodulin and protein C) are decreased. Thus, a propensity for platelet activation and aggregation, coupled with a tendency for coagulation, amplify the risk that plaque rupture result in thrombotic occlusion of arteries (Figure 12).

Non-atherosclerotic CVD
Diabetic cardiomyopathy
Metabolic perturbations in the myocardial cell are the most probable causes for myocardial dysfunction in patients with diabetes. The dominant pathway for myocardial energy production is beta-oxidation of FFAs, but the myocardium is also to a lesser extent dependent on glucose oxidation (Figure 13).

When the heart is subjected to ischaemic stress or exposed to sustained enhancement of intraventricular pressure, its ATP production changes towards a more dominant glucose oxidation. In diabetes, glucose for energy production is, however, substantially lower, accounting for only about 10% of the myocardial energy production. The shift to a more pronounced beta-oxidation of FFA causes therefore a higher oxygen utilization than under normal circumstances. Thus, in diabetes and heart failure, the heart is exposed to increased concentrations of FFAs, released via stress influenced by an increased sympathetic tone as well as through insulin resistance and insulin deficiency-enhancing lipolysis. It has been proposed that prolonged intracellular accumulation of FFA and its metabolites may cause myocardial dysfunction. Diabetic patients are also known to have increased risk for other disturbances such as reduced myocardial blood flow and blunted hyperkinetic response to myocardial ischaemia.
Cardiac autonomic neuropathy

Autonomic neuropathy is a serious and common complication of diabetes. It has been estimated that about 20% of asymptomatic diabetic patients have abnormal cardiovascular autonomic function. The risk for cardiovascular autonomic neuropathy depends on the duration of diabetes and the degree of glycemic control. It is caused by injury to the autonomic nerve fibres that innervate the heart and blood vessels. The hypotheses concerning the aetiology of cardiovascular autonomic neuropathy include metabolic insult to nerve fibres, neurovascular insufficiency, neurohormonal growth factor deficiency, and autoimmune damage. Main consequences are dysfunctional heart rate control, abnormal vascular dynamics, and cardiac denervation, which become clinically overt as exercise intolerance, orthostatic hypotension, intraoperative cardiovascular lability, and silent myocardial ischaemia.

The earliest sign is often a vagal deficiency leaving sympathetic innervation unopposed. A manifestation of this is that diabetic patients tend to have higher resting heart rate and less heart rate variability during the day than their non-diabetic counterparts. A clinical setting where this may be particularly unfavourable is at the onset of an MI causing unnecessary myocardial oxygen consumption in a situation with decreased nutritional blood supply.

The autonomic nervous system influences coronary blood flow regulation independently of endothelial cell function. Diabetic patients with sympathetic nervous system dysfunction have impaired dilatation of coronary resistance vessels in response to cold pressure testing when compared with diabetics without defects in cardiac adrenergic nerve density. Global myocardial blood flow and coronary flow reserve studied by positron emission tomography in response to adenosine provocation were subnormal in diabetics with cardiovascular autonomic neuropathy. It is obvious that cardiovascular autonomic neuropathy may provoke ischaemic episodes by upsetting the balance between myocardial supply and demand. Due to autonomic neuropathy, silent myocardial ischaemia is prevalent in diabetic patients and often symptomatically apparent only in advanced stages of the disease. Instead of typical angina, patients often complain of shortness of breath, diaphoresis, or profound fatigue.

Knowledge on the actual prevalence of cardiovascular autonomic neuropathy and cardiovascular autonomic neuropathy-related mortality rates are conflicting. However, different studies and meta-analysis reveal that mortality rates among diabetic subjects with cardiovascular autonomic neuropathy are many times higher than among those without. Subjects with diabetes and low levels of autonomic function parameters (baroreflex sensitivity, heart rate variability, and classical Ewing tests) had an approximately doubled risk of mortality in the Hoorn Study. In the Detection of Ischaemia in Asymptomatic Diabetics Study, cardiac autonomic dysfunction, assessed by the Valsalva manoeuvre, was a strong predictor of ischaemia, whereas traditional and emerging risk factors were not. Impaired angina perception largely accounts for such an increased mortality. Indeed, silent myocardial ischaemia delays treatment of acute coronary events and makes it more difficult to monitor anti-ischaemic treatment or determine whether restenosis has occurred after a coronary intervention. Although silent, myocardial ischaemia has a reported prevalence of 10–20% in diabetic vs. 1–4% in non-diabetic populations, routine screening for silent myocardial ischaemia in diabetics remains debatable. In the Detection of Ischaemia in Asymptomatic Diabetics Study, 22% of 522 type 2 diabetic patients randomized to adenosine stress testing with myocardial perfusion imaging by means of SPECT had silent ischaemia. This would indicate that asymptomatic diabetic patients have at least an intermediate probability of CAD, a prevalence that has been considered as justifying routine screening for CAD by non-invasive testing. In a series of 203 diabetic patients, the prevalence of functional silent myocardial ischaemia, assessed by stress ECG and thallium myocardial scintigraphy, was 15.7%. In this study, the positive predictive value of exercise ECG was 90%, compared with 63% of thallium myocardial scintigraphy. Thus, available evidence highlights the need for non-invasive screening by means of stress-testing in diabetic subjects, especially considering the high sensitivity, feasibility, and low costs of exercise ECG.

Based on cardiovascular autonomic neuropathy-associated coronary blood flow impairment, misdiagnosed CAD, and the consequently higher risk of mortality, it is presently recommended that a baseline determination of cardiovascular autonomic function is performed upon diagnosis in type 2 diabetes and within 5 years of diagnosis for type 1 diabetes, followed by yearly repeated tests.

Metabolic syndrome

In 1988, Reaven noted that several risk factors (e.g. dyslipidaemia, hypertension, hyperglycaemia) commonly cluster together. He defined this clustering as Syndrome X, and identified it as a risk factor for CVD. Presently, there is an ongoing debate whether this clustering of cardiovascular risk factors represents a disease entity in its own right. However, in clinical practice, it helps identifying individuals at high-risk for CVD and type 2 diabetes. In the following, the concept of the metabolic syndrome is reviewed.

*Overweight and obesity are associated with insulin resistance and the metabolic syndrome. However, the presence of abdominal obesity is more highly correlated with the metabolic risk factors than is an elevated BMI. Therefore, the simple measure of waist circumference is recommended to identify the body weight component of the metabolic syndrome.

bSome male patients can develop multiple metabolic risk factors when the waist circumference is only marginally increased, e.g. 94–102 cm (37–39 in.). Such patients may have a strong genetic contribution to insulin resistance. They should benefit from changes in life habits, similarly to men with categorical increases in waist circumference.

The ADA has recently established a cut-point of ≥ 100 mg/dL, above which persons have either pre-diabetes (IFG) or diabetes. This new cut-point should be applicable for identifying the lower boundary to define an elevated glucose as one criterion for the metabolic syndrome.

Nowadays, extended panels of metabolic risk factors have been identified in order to better understand pathogenesis, predict outcomes, and improve clinical management of the so-called metabolic syndrome. Two independent efforts to identify definition criteria have been carried out by the National Cholesterol Education Programme’s Adult Treatment Panel III (ATP III)126 and the World Health Organization (WHO).122

ATP III identified six components of the metabolic syndrome that relate to CVD: (i) abdominal obesity; (ii) atherogenic dyslipidaemia; (iii) raised blood pressure; (iv) insulin resistance and/or glucose intolerance; (v) pro-inflammatory state; and (vi) prothrombotic state.

Table 8 Criteria for metabolic syndrome according to International Diabetes Federation130

| Central obesity (defined as waist circumference ≥ 94 cm for Europid men and ≥ 80 cm for Europid women, with ethnicity specific values for other groups) |
|---|---|
| Plus any two of the following factors |
| Raised TG level: ≥ 1.7 mmol/L (150 mg/dL), or specific treatment for this lipid abnormality |
| Reduced HDL cholesterol: < 1.03 mmol/L (< 40 mg/dL) in males and < 1.29 mmol/L (< 50 mg/dL) in females, or specific treatment for this lipid abnormality |
| Raised blood pressure: systolic BP ≥ 130 or diastolic BP ≥ 85 mm Hg, or treatment of previously diagnosed hypertension |
| Raised FPG > 5.6 mmol/L (100 mg/dL), or previously diagnosed type 2 diabetes |
| If above 5.6 mmol/L or 100 mg/dL, OGTT is strongly recommended, but is not necessary to define presence of the syndrome |

*In future, epidemiological studies of populations of Europid origin, prevalence should be given using both European and North American thresholds to allow better comparisons.

All of these components are part of a larger body of risk factors for CVD that ATP III identifies as underlying (obesity, physical inactivity, atherogenic diet), major (cigarette smoking, hypertension, elevated LDL cholesterol, low HDL cholesterol, family history of premature CHD, aging), and emerging (elevated triglycerides, small LDL particles, insulin resistance, glucose intolerance, pro-inflammatory state, and prothrombotic state).

In order to facilitate diagnosis and preventive interventions, ATP III proposed a clinical definition based on having at least three of five criteria (Table 6). Using ATP III definition, the estimated prevalence of the metabolic syndrome among men and women in NHANES III120 ranges from 5%
(normal weight) to 60% (obese) in men, and from 6% (normal weight) and 50% (obese) in women. Currently, it exceeds 20% of individuals who are at least 20 years of age, and 40% of the population >40 years.271

The WHO criteria (Table 7) require insulin resistance for diagnosis, by demonstrating the presence of type 2 diabetes, IFG, or IGT by OGTT in patients without IFG. In addition to insulin resistance, two other risk factors are sufficient for the diagnosis of metabolic syndrome.

On the contrary, ATPIII claims that information obtained from OGTT does not outweigh the inconveniences and costs by applying this test in clinical practice.

Notably, both ATPIII and WHO recognize CVD as the primary outcome of the metabolic syndrome. In the Framingham Study, the metabolic syndrome alone predicted 25% of all new-onset CVD. In the absence of diabetes, the metabolic syndrome generally did not raise the 10-year risk for CAD to >20% (the threshold for ATPIII CAD risk equivalent). Notably, the 10-year cardiovascular risk in men with metabolic syndrome ranged from 10–20%, whereas it did not exceed 10% in most women, who also displayed a lower rate of CAD events during the 8-year follow-up.

In April 2005, a group of experts invited by the International Diabetes Federation (IDF) released a unified definition for the metabolic syndrome seeking worldwide acceptance and potential application.130

To be defined as having the metabolic syndrome according to the new definition, a person must present as outlined in Tables 8 and 9.

While the pathogenesis of the metabolic syndrome and each of its components is complex and not well understood, central obesity and insulin resistance are acknowledged as important causative factors. Abdominal circumference, a sine qua non condition for diagnosis of the syndrome, is the clinical screening factor for the metabolic syndrome. Abdominal obesity is much more associated with metabolic risk factors than BMI. The IDF consensus group has highlighted a number of other parameters that appear to be related to the metabolic syndrome which should be included in research studies to help determine the predictive power of these extra criteria for CVD and/or diabetes. As outlined earlier, none of the definitions of the metabolic syndrome has been validated prospectively.

**Obesity**

Abdominal obesity, as detected by increased waist circumference, is the first criterion listed. Its inclusion reflects the pivotal role assigned to abdominal obesity as a contributor to metabolic syndrome: obesity contributes to hypertension, high serum cholesterol, low HDL cholesterol and hyperglycaemia, and it associates with higher CVD risk. Excess visceral adipose tissue releases several products that apparently exaggerate these risk factors including FFAs, which overloads muscular and liver tissues with lipid, thus enhancing insulin resistance; PAI-1, which contributes to a prothrombotic state; CRP, which may signify cytokine excess and a pro-inflammatory state. The strong connection between abdominal obesity and risk factors led ATPIII to define the metabolic syndrome essentially as a cluster of metabolic complications of obesity.

**Insulin resistance**

Insulin resistance per se is believed to play a significant role in the pathogenesis of the metabolic syndrome, and many investigators claim that insulin resistance is the pathophysiological process behind the clustering of cardiovascular risk factors in the metabolic syndrome.272 Insulin resistance predicts atherosclerosis and cardiovascular events independently of other risk factors, including fasting glucose and lipid levels.273 However, so far there is little evidence that a reduction in insulin resistance will substantially improve any of the components of the metabolic syndrome other than glucose intolerance. Moreover, identifying a unique role for insulin resistance is complicated by the fact that it is often linked to obesity. Thus, the putative mechanistic link between insulin resistance and most of the components of the metabolic syndrome remains unclear and does not meet general consensus. Mechanisms by which insulin resistance impacts other metabolic syndrome risk factors are: (i) diversion of excess FFAs from lipid-overloaded insulin-resistant muscles to the liver, thus promoting fatty liver and atherogenic dyslipidaemia; (ii) enhanced output of VLDL; (iii) predisposition to glucose intolerance, which can be worsened by increased hepatic gluconeogenesis in the insulin-resistant liver; (iv) increasing blood pressure.

Insulin resistance generally rises with increasing body fat and most people with a BMI ≥30 kg/m² have postprandial hyperinsulinaemia/reduced insulin sensitivity,274 whereas persons with a BMI of 25–29.9 kg/m² exhibit a spectrum of insulin sensitivities as well. In some populations (such as South Asians), insulin resistance is common even with BMI <25 kg/m², a condition termed primary insulin resistance.

To reduce insulin resistance is an attractive pharmacological target to prevent CVD in metabolic syndrome patients currently with two classes of drugs available: metformin and insulin sensitizers, such as thiazolidinediones (TZDs). Both drugs reduce insulin resistance and favourably impact different metabolic risk factors. However, no clinical trial documented the efficacy of metformin and TZDs in reducing CVD risk, thus limiting recommendation for their use in preventing CVD in patients with either the metabolic syndrome or diabetes. Anyhow, good glycaemic control obtained through drug therapy and lifestyle changes is mandatory.

**Atherogenic dyslipidaemia**

Atherogenic dyslipidaemia is often recognized in the metabolic syndrome and manifests itself by raised triglycerides, low HDL cholesterol, increased remnant lipoproteins, elevated apolipoprotein B, small LDL, and small HDL particles. It is commonly believed that hypertriglyceridaemia is due to enhanced triglyceride hepatic synthesis driven by an increased flux of FFAs from the periphery to the liver in an insulin-resistant setting.275 The causes of hypertriglyceridaemia in the metabolic syndrome are, however, most likely multifactorial and the increased FFA flux-hypothesis is only one side of this issue. In the same view, low HDL cholesterol, often ascribed to elevated TG because of increased transfer of TG to HDL and cholesterol from HDL,276 are likely to have a more complex origin, since HDL cholesterol levels are often reduced in patients with insulin resistance even when fasting TG levels are normal.
More recently, activation of innate immunity and immunity-related inflammation have been proposed as potential links between insulin resistance and dyslipidaemia. In animal models activation of innate immunity leads to changes in lipoproteins, enzymes, transfer proteins, and receptors\textsuperscript{277} commonly seen also in human metabolic syndrome. Inflammation-driven increase in lipase production has been proposed as a mechanism promoting reduction of lipid content of HDLs.\textsuperscript{278}

**High blood pressure**

In obese patients, blood pressure is sensitive to sodium intake, and this sensitivity is related to fasting insulin levels.\textsuperscript{279} The anti-natriuretic effect of insulin, together with its ability to activate the sympathetic nervous system\textsuperscript{280} and to drive abnormal vascular function contributes to the development of hypertension. Moreover, both hyperglycaemia and insulin activate the renin–angiotensin system (RAS) by enhancing the expression of angiotensinogen, angiotensin II, and AT1 receptor, which contributes to an increase in blood pressure in patients with insulin resistance.

**Proinflammatory and prothrombotic state**

Chronic subclinical inflammation is part of the metabolic syndrome.\textsuperscript{281} This condition is characterized by elevated cytokines (e.g. TNF-alpha and IL-6) and acute-phase reactants (C-reactive protein and fibrinogen). Of interest, recent studies suggest that immunity and inflammation play a role in the development of insulin resistance and predict the development of type 2 DM.\textsuperscript{282,283} Thus, the pathogenesis of insulin resistance and metabolic syndrome risk factors may have a common inflammatory basis, which closely relates to the occurrence of atherosclerotic cardiovascular events. Since measures of inflammatory activity do not presently provide additional insights into the risk of events in metabolic syndrome patients, the current clinical approach to the metabolic syndrome does not incorporate measurement of inflammatory markers. However, as elevated C-reactive protein levels (\(\geq 3\) mg/L) have been outlined as an emerging risk factor for CVD, its inclusion together with traditional metabolic syndrome risk factors into a single algorithm is likely to provide a useful approach to risk prediction in metabolic syndrome patients. Indeed, in a recently published study\textsuperscript{284} plasma C-reactive protein levels provided prognostic information regarding the risk of cardiovascular events in apparently healthy women at all levels of severity of the metabolic syndrome.

A prothrombotic state in patients with the metabolic syndrome is characterized by elevations of fibrinogen, PAI-1, and possibly other coagulation factors. In the metabolic syndrome, activation of NF-kB promotes synthesis of PAI-1, a natural inhibitor of tissue plasminogen activator, and leads to impaired fibrinolysis. PAI-1 levels correlate with plasma insulin levels and insulin resistance, and appear to predict the likelihood of developing diabetes.\textsuperscript{285} Since no drugs are available that target PAI-1 and fibrinogen, the alternative approach to the prothrombotic state is antiplatelet therapy.

**Treatment to reduce cardiovascular risk**

**Life style and comprehensive management**

Long-term hyperglycaemia, i.e. DM—both type 1 and type 2—is strongly associated with specific microvascular complications of the retina and the kidneys on one side, and with abundant macrovascular disease of the heart, brain, and lower limbs as well as with neuropathy of the autonomic and peripheral nerve system on the other.\textsuperscript{286–294} Macrovascular events are about 10 times more common than severe microvascular complications, and already occur at excessive rates in patients with glucometabolic disturbances, even before the onset of overt type 2 diabetes.\textsuperscript{295–297} Hyperglycaemia is only one of a cluster of vascular risk factors which often is referred to as the metabolic syndrome.\textsuperscript{118,131,135,300} Hence, treatment modalities have to be rather complex and strongly based on non-pharmacological therapy including life style changes and self-monitoring and it requires structured patient education.\textsuperscript{301–305} This has to include a heavy emphasis on smoking cessation.

Implementation of a healthier life style with an increase in physical activity and a reduction of body weight, based on the regulation of calories and fat intake, are the basis for the prevention of type 2 diabetes,\textsuperscript{108,109,306,307} and the same principles apply to basic treatment of type 2 diabetes.\textsuperscript{301,302} Prior to treatment randomization, patients enrolled into the UKPDS, still to date the largest prospective treatment study in type 2 diabetes, underwent 3 months of non-pharmacological treatment with emphasis on life-style changes. Along with an average decrease of about 5 kg body weight, HbA1c decreased about 2% to an
absolute value close to 7%. Hence, non-pharmacological therapy seems to be at least as effective as any glucose-lowering drug therapy, which yields a mean \( \text{HbA}_1c \) lowering effect of 1.0–1.5% in placebo-controlled randomized studies (Table 10). Accordingly, non-pharmacological life style-oriented therapy is the foundation of all successful glucose-lowering regimens.

The specific recommendations include 30 min of physical activity at least five times a week, restriction of calorie intake to \( \sim 1500 \text{ kcal/day} \), restriction of fat intake to 30–35% of total daily energy uptake (reservation of 10% for monounsaturated fatty acids, e.g., olive oil), avoidance of trans fats, increased fibre uptake to 30 g/day, and the avoidance of liquid mono- and disaccharides.

Risk stratification according to the coexistence of the metabolic syndrome and its individual features, or for concomitant-associated hypertension, dyslipidaemia, and microalbuminuria is mandatory for comprehensive management of patients with diabetes. The recognition of the underlying insulin resistance with increased visceral adiposity is a key factor for an appropriate therapy, not only of hyperglycaemia but also of hypertension and dyslipidaemia. The suggested new global definition of the metabolic syndrome, as recently released by the International Diabetes Federation, is depicted in Table 6 (see section on Pathophysiology). Using this approach and applying multiple risk factor interventions to high-risk type 2 diabetic patients, as done in the Steno 2 Study, is extremely compelling in terms of overall outcome. Targeting hyperglycaemia, hypertension, and dyslipidaemia together with the administration of acetylsalicylic acid to high-risk patients with established microalbuminuria resulted in a more than 50% reduction of major macrovascular events (fatal and non-fatal MI and stroke) with an NNT of as low as five over a 8-year long period \( (P = 0.008) \). This multiple risk factor intervention approach proved highly effective in less than 4 years in terms of microvascular outcomes, thereby confirming the results of UKPDS. Still, the ability to achieve pre-defined targets in Steno 2 was far from complete and strikingly variable. By far, the most difficult target to achieve was \( \text{HbA}_1c \) (Figure 14).

This notion was also apparent in the UKPDS, fostering the concept of glucose-lowering polypharmacy, like antihypertensive therapy (see below). To reach targets is the crucial objective of comprehensive management. In this context and, in addition, every diabetic patient with some indication of vascular damage–be it macrovascular or microvascular–should be considered for antiplatelet drug therapy, especially acetylsalicylic acid. Further details on target levels are outlined in Table 9. It should be noted that failure to reach the target \( \text{HbA}_1c \) level should be avoided, and that early escalation of glucose-lowering therapy is essential.

Closing the gap between the complex needs of comprehensive management in high risk and multimorbid individuals with type 2 diabetes and the challenges in daily life, intensive counselling of patients is mandatory. These patients are not infrequently prescribed up to 10 different classes of drugs in addition to the counselling of a healthy lifestyle. Structured therapy, including educational classes and training programmes for acquiring the skills for a healthy lifestyle and self-monitoring of blood glucose and blood pressure are an indispensable pre-requisite for successful management and therapy. A mutual reviewing of the self-management protocols at each patient visit allows physicians and patients to become partners in treatment. Paramedical personnel e.g. certified diabetes educators and nurses play an integrated role in this quality process. Successful comprehensive management of patients with diabetes requires a framework of quality structures with auditing of processes and outcomes. Certified quality management should be reinforced by appropriate incentives both for the patient and the physician.

**Recommendation**

Structured patient education improves metabolic and blood pressure control. Class I, Level of Evidence A.

Non-pharmacological life style therapy improves metabolic control. Level A, Class I.

Self-monitoring improves glycaemic control. Class I, Level of Evidence A.

**Glycaemic control**

**Relation to microangiopathy and neuropathy**

RCTs have provided compelling evidence that diabetic microangiopathy and neuropathy can be reduced by tight glycaemic control. This will also exert a favourable influence on CVD. Nephropathy accelerates CVD and autonomic neuropathy may mask its symptoms. When compared to conventional treatment regimens, intensified treatment options, aimed at lowering haemoglobin \( \text{HbA}_1c \) close to the normal range, have consistently been associated with a markedly decreased frequency and extent of microvascular and neuropathic complications in people with type 1 and type 2 diabetes. Not only does this apply to primary, but also to secondary
intervention. Analyses from the Diabetes Control and Complication Trial (DCCT) and the UKPDS demonstrated a continuous relationship between HbA1c and microangiopathic complications without any apparent threshold of benefit. In the DCCT, a 10% reduction of HbA1c was associated with a 40–50% lower risk of retinopathy or its progression, although the absolute reduction in risk was substantially less at lower HbA1c levels, e.g. below 7.5%. The UKPDS reported a linear relationship with each 1.0% lower HbA1c associated with a 25% decline in the risk of microvascular complications, again with a rather low absolute risk at HbA1c levels below 7.5%. These notions were also underlined by earlier European studies in type 1 diabetes as well as the Kumamoto and the Steno 2 studies in type 2 diabetes. Microvascular complications, both at the kidney and the eye level, warrant meticulous further therapeutic measures, including adequate control of blood pressure with the use of ACE-inhibitors and/or angiotensin receptor-II-blockers and the cessation of smoking. Accordingly, screening for microalbuminuria and retinopathy is mandatory on an annual basis.

Relation to macroangiopathy

Although rather suggestive, the relation between macrovascular disease and hyperglycaemia is less clear than the relation to microangiopathy. In fact, the recent DCCT open post-study long-term follow-up over 11 years (EDIC Study) convincingly demonstrated that a randomly assigned intervention, aiming at tight glycaemic control (mean HbA1c close to 7% over the first 7-10 years), effectively reduced cardiac and other macrovascular disease manifestations from 98 events in 52 patients to 46 events in 31 patients, corresponding to a decrease of 42%. The risk for MI and stroke, as well as the mortality risk from CVD, was reduced by 57%. This result was achieved despite a less tight control during the last years of follow-up when mean HbA1c was around 8%. This important finding was based on a 93% follow-up rate of the original cohort of 1441 patients with type 1 diabetes and comparable levels of blood pressure and blood lipid control. The only significant confounding factor was a higher rate of microalbuminuria and macroproteinuria in the less well-controlled group (complications that are dependent on glycaemic control on their own). On statistical grounds, the reduction of HbA1c was by far the most important factor behind the reduction of CVD with a 21% reduction for each percent decrease of HbA1c.

In type 2 diabetes, as shown by the UKPDS, each percent decrease of HbA1c was associated with a 25% decline in the risk of macrovascular complications, again with a rather low absolute risk at HbA1c levels below 7.5%. These notions were also underlined by earlier European studies in type 1 diabetes as well as the Kumamoto and the Steno 2 studies in type 2 diabetes. A wealth of reports indicate that a random blood sugar on admission for an acute coronary syndrome (ACS) is strongly correlated with the short- and long-term outcome of these patients. Higher blood sugar concentrations in persons with diabetes, including those previously undiagnosed, are highly predictive for poorer outcome both in the hospital and subsequently. The landmark Diabetes Glucose And Myocardial Infarction (DIGAMI) Study performed in patients with an ACS, targeted acute hyperglycaemia on admission in a randomized fashion by means of an insulin–glucose infusion. Within 24 h, glycaemia was significantly lower in the intervention group, to be maintained at a lower level during the next year. This difference translated into a 11% reduced mortality in absolute terms, indicating an NNT of nine patients for one life saved. The beneficial effect was still apparent after 3.4 years with a relative mortality reduction of about 30%.

DIGAMI 2 confirmed that glycaemic control is highly predictive for the 2-year mortality rate, but did not show any clinically relevant differences between different blood glucose-lowering regimens. A recently published study, however, with a follow-up of only 3 months, confirmed that the mean
achieved blood glucose is relevant for mortality in diabetic post-MI patients, whereas insulin therapy per se did not lower mortality.66

Targeting acute hyperglycaemia in diabetic patients with ACS was also introduced into the Schwabing Myocardial Infarction Registry. Provided that all other potential interventions were equally applied to non-diabetic and diabetic patients, 24 h mortality among the diabetics was normalized and total in-hospital mortality the same for the patients with and without diabetes.327

Current treatment approach to glycaemic control
In type 1 diabetes, the gold standard of therapy in the post-DCCT era is intensified insulin therapy, based on appropriate nutrition and blood glucose self-monitoring, aiming at HbA1c below 7%. Episodes of hypoglycaemia need to be titrated against this goal and severe hypoglycaemic episodes should be kept below a rate of 15/100 patient-years.310,328

In type 2 diabetes, a common pharmacologic treatment approach is less well-accepted. Various diabetes associations have advocated HbA1c targets below 7.0 or 6.5%, respectively (Table 11).310,328,329

Disappointingly, only a minority of patients achieved proposed glucose targets during long-term follow-up in studies like the UKPDS or Steno 2.71,309 The greatest advance in the treatment of type 2 diabetes in recent years is the advent of polypharmacy, originally suggested by the UKPDS investigators.310 A concept of early combination therapy has been put forward intended to maximize efficacy and minimize side-effects. It is based on the fact that a medium dose yields about 80% of the glucose-lowering effect, still minimizing potential side-effects such as weight gain, gastrointestinal discomfort, and the risk for hypoglycaemia.331 This includes early initiation to insulin if oral glucose-lowering drugs in appropriate doses and combinations, backed by appropriate life style therapy, fails to reach target. BMI and the risks of hypoglycaemia, renal insufficiency, and heart failure are major determinants for the choice of treatment (Table 11).

In addition, the stage of the disease and the related preponderant metabolic phenotype should be considered when tailoring therapy to individual needs (Table 13).331–334

A strategy for the selection of various glucose-lowering pharmacological options based on an assumption or, if available, more detailed knowledge on the glucometabolic situation is outlined in Table 13. The use of metformin has emerged as an important option both for mono- and combination therapy including insulin, provided that contraindications for this compound are absent.331

Successful multicomponent glucose-lowering therapy requires self-monitoring of blood glucose to ensure that metabolic targets are met. Again, the regimen of blood glucose self-monitoring depends on the choice of therapy used and the metabolic phenotype. Obviously, when near-normoglycaemia is the goal, post-prandial glycaemia needs to be taken into account in addition to fasting glycaemia. Monnier et al.313 have shown that to achieve good glycaemic control of HbA1c < 8% requires measures that lower post-prandial glucose excursion, i.e. treatment that only improves the fasting glucose level will not be sufficient. Blood glucose monitoring is also advantageous in type 2 diabetic patients without insulin treatment, as evidenced by recent meta-analyses.311,312

There is an ever increasing body of evidence that a target close to the normal glycaemic level is advantageous for reducing CVD in people with diabetes. Still, proof of efficacy for primary prevention awaits confirmation. The glycaemic targets recommended for most persons with type 1 and type 2 diabetes are listed in Table 11. They should, however, be tailored to individual needs, especially in view of the risk of hypoglycaemia and other compound-specific side-effects of therapy. Immediate action, including the use of insulin infusion, is mandatory in patients with ACS and may require the joint approach of an endocrinologist and a cardiologist. In the long-term, provided it can be safely achieved, lowering blood glucose toward the normal range should be considered; this might need special targeting of post-prandial hyperglycaemia.

bLevel of evidence.

Background and epidemiology
As part of the metabolic syndrome and the pre-diabetic state, dyslipidaemia in type 2 diabetes is often present at the time of diagnosis. It persists despite the use of hypoglycaemic therapy and requires specific therapy with diet, lifestyle, and hypolipidaemic drugs. It is characterized by quantitative and qualitative changes in lipid and lipoproteins, which are correlated with insulin resistance. Typically, there is moderate hypertriglyceridaemia, low HDL cholesterol, and abnormal post-prandial lipaemia. Total and LDL cholesterol levels are similar to those in subjects without diabetes, however, LDL particles are small and dense, which is associated with increased atherogenicity and there is accumulation of cholesterol-rich remnant particles, which are also atherogenic.

Dyslipidaemia is a common finding in type 2 diabetes. The Botnia Study, for instance, included 4483 men and women aged 35–70 years, of which 1697 had diabetes and 798 IFG. The prevalence of low HDL cholesterol ([<0.9 mmol/L (35 mg/dL) in men and <1.0 mmol/L (39 mg/dL) in women] and/or elevated plasma triglycerides [>1.7 mmol/L (151 mg/dL)]) was up to three times higher in those with diabetes and two times higher in those with IFG compared to those with normal glucose tolerance. In this and other studies the prevalence of dyslipidaemia was more pronounced in women than in men.

Dyslipidaemia and vascular risk
Although total and LDL cholesterol concentrations in patients with type 2 diabetes are similar to subjects without diabetes, they are important vascular risk factors. Observational data from the UKPDS demonstrated that a 1 mmol/L (38.7 mg/dL) increase in LDL cholesterol was associated with a 57% increase in CVD endpoints. Low HDL cholesterol was also an important predictor of vascular disease in UKPDS, a 0.1 mmol/L (4 mg/dL) increase being associated with a 15% decrease in CVD endpoints.

The independent relationship of elevated plasma triglycerides to vascular risk remains controversial. However, given the complex interactions between triglycerides and other lipoproteins and the inherent variation in triglyceride concentrations, it is clear that determining the independence of the triglyceride/vascular disease relationship by mathematical modelling, such as multivariate regression analyses is likely to be fraught with problems. In a meta-analysis of population-based cohort studies, average excess risk associated with a 1 mmol/L (89 mg/dL) increase in triglycerides was 32% in men and 76% in women. When adjusted for HDL cholesterol, the excess risk was halved to 37% in women and 14% in men, but remained statistically significant. High triglyceride levels and low HDL cholesterol were significantly related to all CHD events and to coronary mortality in a large cohort of patients with type 2 diabetes followed for 7 years. Factor analysis and principal component analysis have shown that a ‘hyperinsulinaemia cluster’ (a factor having high positive loadings for BMI, triglycerides, and insulin and a high negative loading for HDL cholesterol) was predictive of CHD mortality in type 2 diabetes.

Treatment benefits of statin therapy
The introduction of the statin drugs, which proved to be well-tolerated and highly effective, enabled definitive RCTs of LDL cholesterol-lowering to be undertaken. These
drugs are specific, competitive inhibitors of the enzyme 3-hydroxy-3-methylglutaryl coenzyme A reductase (HMG CoA reductase), which catalyzes the major rate determining step in cholesterol synthesis. As a result, hepatic LDL receptor activity increases with consequent increased uptake of LDL cholesterol and decreased plasma LDL-cholesterol. The statins are the most potent drugs for lowering plasma LDL-cholesterol.

Secondary prevention

Although no major secondary prevention trial has been performed in a specific diabetic population, there is sufficient evidence from post hoc subgroup analysis of over 5000 patients with diabetes, included in the major trials, to conclude that they show similar benefits in reduction of events (both coronary events and stroke) as patients free from diabetes.

The first landmark secondary trial was the Scandinavian Simvastatin Survival Study (4S), which included patients \( n = 4444 \) with established CAD and total cholesterol concentrations between 5.5 and 8 mmol/L (193 and 309 mg/dL) despite dietary therapy.\(^{341}\) The study was powered on overall mortality. This study was a randomized, placebo-controlled trial comparing simvastatin to placebo. The goal of therapy in the simvastatin group was total cholesterol between 3.0 and 5.2 mmol/L (116 and 201 mg/dL). Thirty seven percent of patients required simvastatin 40 mg/day to achieve target cholesterol levels. Simvastatin therapy was associated with a 35% reduction in LDL-cholesterol. After a median follow-up of 5.4 years, the impact of simvastatin on the primary endpoint of overall mortality, although there was a non-significant 43% reduction.\(^{342}\) A further analysis of 45 identified 483 diabetic patients by baseline plasma glucose. In this cohort, there was a significant 42% reduction in major coronary events and a 48% reduction in revascularizations.\(^{343}\)

These initial results have been supported by subsequent secondary prevention trials, particularly the Heart Protection Study (HPS; Table 14). It is clear that patients with diabetes show similar RRRs compared to those without diabetes. Given the higher absolute risk in these patients, the NNT to prevent a CVD event is lower. However, the residual risk in diabetic patients remains high, despite statin treatment. For example, in HPS, the residual risk during the study period was higher in diabetic patients with vascular disease treated with simvastatin compared to patients with vascular disease, but no diabetes treated with placebo.\(^{344}\)

When the results of the statin trials are related to the degree of LDL reduction, the results show a roughly linear relationship. More recently, the potential added benefit of achieving LDL cholesterol concentrations lower than levels previously achieved has been tested. In the Pravastatin or Atorvastatin Evaluation and Infection Therapy (PROVE-IT) Trial, standard statin therapy (pravastatin 40 mg/day) was compared to intensive therapy (atorvastatin 80 mg/day) in 4162 patients within 10 days of an ACS, with a mean

CHD = coronary heart disease; CHF = congestive heart failure; MI = myocardial infarction; revas = revascularisation; UAP = unstable angina pectoris.
follow-up of 24 months.\textsuperscript{345} More intensive therapy [achieved mean LDL 1.6 mmol/L (62 mg/dL)] was associated with a significant 16% risk reduction in cardiovascular events, compared to standard therapy [mean LDL 2.5 mmol/L (97 mg/dL)]. \textsuperscript{345} PROVE-IT included 734 diabetic patients (18%) and there was no heterogeneity of effect in this subgroup.

Treat to New Targets Trial (TNT) has reported on the effects of intensive statin therapy (atorvastatin 80 mg/day), compared to standard therapy (atorvastatin 10 mg/day), in 10,001 patients with stable CAD.\textsuperscript{346} Intensive therapy [mean LDL cholesterol 2.0 mmol/L (77 mg/dL)] was associated with a 22% risk reduction compared to standard therapy [mean LDL cholesterol 2.6 mmol/L (101 mg/dL)], over a median follow-up of 4.9 years. In a recent subgroup analysis of the TNT, the results of intensive, compared to standard, atorvastatin therapy were reported for the 1501 patients with diabetes, 735 received atorvastatin 10 mg/day, and 748 atorvastatin 80 mg/day. By the end-of-treatment, mean LDL cholesterol levels were 2.6 mmol/L (99 mg/dL) with atorvastatin 10 mg and 2.0 mmol/L (77 mg/dL) with atorvastatin 80 mg. A primary event occurred in 135 patients (17.9%) receiving atorvastatin 10 mg, compared with 103 patients (13.8%) receiving atorvastatin 80 mg (HR 0.75, P = 0.026). Significant differences between the groups in favour of atorvastatin 80 mg were also observed for time to cerebrovascular event [0.69 (0.48–0.98), P = 0.037] and any cardiovascular event [0.85 (0.73–1.00), P = 0.044].\textsuperscript{341}

**Goals of therapy for secondary prevention**

Based on evidence from RCTs, the Third Joint European Societies Task Force on Cardiovascular Disease Prevention in Clinical Practice\textsuperscript{347} recommended treatment goals for patients with established CVD of total cholesterol <4.5 mmol/L (174 mg/dL) and LDL-cholesterol <2.5 mmol/L (97 mg/dL). This LDL goal is similar to that of the Adult Treatment Panel III (ATP III) of the Cholesterol Education Programme in the USA.\textsuperscript{348} More recently, guidelines have been reviewed by the National Cholesterol Education Programme, in the light of recent RCTs.\textsuperscript{348} Thus, for very high-risk patients, including those with diabetes and symptomatic CVD, a therapeutic option of an LDL goal ≤1.8 mmol/L (70 mg/dL) is suggested.

**Recommendation**

Elevated LDL- and low HDL-cholesterol are important risk factors in people with diabetes. Class I, Level of Evidence A.

Statins are first-line agents for lowering LDL-cholesterol in diabetic patients. Class I, Level of Evidence A.

In diabetic patients with CVD, statin therapy should be initiated regardless of baseline LDL-cholesterol with a treatment target of ≤1.8 mmol/L. Class I, Level of Evidence B.

**Primary prevention**

Given the high risk of CVD in diabetic patients, together with a higher mortality associated with the first event, primary prevention with lipid-lowering is an important component of global preventive strategies in patients with type 2 diabetes.

Information from RCTs is available to inform clinical decisions from large cohorts of diabetic patients included in HPS\textsuperscript{344} and the Anglo-Scandinavian Cardiac Outcomes Trial-Lipid Lowering Arm (ASCOT-LLA).\textsuperscript{349} In ASCOT-LLA, 10 mg of atorvastatin was compared with placebo in 10,305 hypertensive patients with non-fasting total cholesterol of 6.5 mmol/L (251 mg/dL) or less, of whom 2532 had type 2 diabetes. Atorvastatin therapy was associated with a 36% reduction in the primary endpoint of non-fatal MI and fatal CAD, after a median follow-up of 3.3 years. Tests for heterogeneity showed that those with diabetes (n = 2532) responded in a similar way, although there were too few events (n = 84) to assess reliably the effect in the subgroup alone. In HPS, there were 2912 diabetic patients without symptomatic vascular disease.\textsuperscript{344} In this cohort, the risk reduction was 33% (P = 0.0003) with simvastatin 40 mg/day.

The Collaborative Atorvastatin Diabetes Study (CARDS), compared atorvastatin 10 mg to placebo, in a population of patients with type 2 diabetes (aged 40–75 years) without high cholesterol [baseline LDL 3.0 mmol/L (116 mg/dL)], but with one other risk factors for CVD: hypertension, retinopathy, proteinuria, or cigarette smoking. After a median follow-up of 3.9 years, the risk reduction in first major cardiovascular events was 37% (P = 0.001). In all three trials there was no heterogeneity of effect with regard to baseline LDL-cholesterol or other lipid values.\textsuperscript{350}

**Goals of therapy for primary prevention**

In the Joint European Guidelines, similar goals of therapy are given for diabetic patients for primary prevention, as for patients with symptomatic disease: cholesterol <4.5 mmol/L (<174 mg/dL) and LDL <2.5 mmol/L (<97 mg/dL). Patients with type 1 diabetes and proteinuria are included in this guidance.\textsuperscript{347} In ATP III, most patients with diabetes without symptomatic disease are considered at high risk and an LDL goal of <2.6 mmol/L (100 mg/dL) is suggested. Given that, diabetic patients in HPS and CARDS with low LDL cholesterol levels showed similar relative benefit with statin therapy to those with higher LDL levels, an important clinical question is whether to start statin therapy in patients whose LDL cholesterol is already 3.0 mmol/L (116 mg/dL), statin therapy to achieve an LDL reduction of 30–40% regardless of baseline LDL levels is recommended.\textsuperscript{351}

In patients with type 1 diabetes, who also have a high lifetime risk of CVD, evidence is still lacking regarding the role of statin therapy for primary prevention.

**Recommendation**

Statin therapy should be considered in adult patients with type 2 diabetes, without CVD, if total cholesterol >3.5 mmol/L (>135 mg/dL), with treatment aiming for an LDL-cholesterol reduction of 30–40%. Class IIb, Level of Evidence B.

Given the high lifetime risk of CVD, it is suggested that all type 1 patients over the age of 40 years should be considered for statin therapy. In patients 18–39 years (either type 1 or type 2), statin therapy should be considered when other risk factors are present, e.g. nephropathy, poor glycaemic control, retinopathy, hypertension, hypercholesterolaemia, features of the metabolic syndrome or
family history of premature vascular disease. Class IIb, Level of Evidence C.

Fibrate trials
There is much less information available from RCTs to determine clinical practice in terms of fibrate therapy compared to statin therapy. A small number of diabetic patients (n = 135) were included in the Helsinki Heart Study (HHS), a primary prevention trial in 4082 men with non-HDL cholesterol (total cholesterol minus HDL cholesterol) >5.2 mmol/L (201 mg/dL) comparing gemfibrozil to placebo. Overall, gemfibrozil was associated with a significant 35% risk reduction. In a post hoc analysis of individuals with a cholesterol/HDL ratio >5 and triglycerides >2.3 mmol/L (>204 mg/dL), there was a 71% reduction in risk. The incidence of non-fatal MI and coronary death was significantly higher during the trial in the small diabetic cohort, but the 68% risk reduction observed with gemfibrozil did not reach statistical significance, given the small numbers.352

In the Veterans Administration HDL Trial (VAHIT), gemfibrozil was compared with placebo in 2531 men with stabilized CAD and low HDL cholesterol [baseline HDL 0.8 mmol/L (31 mg/dL)] and a relatively normal LDL [baseline LDL 2.8 mmol/L (108 mg/dL)]. After a mean follow-up of 5.1 years, gemfibrozil therapy was associated with a 22% risk reduction in the primary endpoint of non-fatal MI or coronary death (P = 0.006). In a subgroup of 309 diabetic patients, a composite endpoint of coronary death, stroke, and MI, was reduced by 32% (coronary death by 41% and stroke by 40%). This trial suggests benefit beyond LDL-lowering, in that gemfibrozil therapy did not change LDL cholesterol, but HDL cholesterol increased by 6% and triglycerides fell by 31%,353,354

The FIELD Study (Fenofibrate Intervention and Event Lowering in Diabetes) assessed the effect of fenofibrate (micronized preparation 200 mg/day) compared to placebo in type 2 diabetes, with (n = 2132) and without (n = 7664) previous CVD.355 After a mean duration of 5 years, fenofibrate therapy was associated with an RRR of 11% (HR 0.89, 95%CI 0.75–1.05) in the primary endpoint of CHD death and non-fatal MI, which did not reach statistical significance (P = 0.16). Non-fatal MI was reduced significantly (HR 0.76, 95%CI 0.62–0.94; P = 0.01), but CHD mortality showed a non-significant increase (HR 1.19, 95%CI 0.90–1.57; P = 0.22). Total cardiovascular events (cardiac death, MI, stroke, coronary and carotid revascularization) were significantly reduced by fenofibrate therapy (P = 0.035). Total mortality was 6.6% in the placebo and 7.3% in the fenofibrate group (P = 0.18). In a post hoc analysis, fenofibrate therapy was associated with a reduction in coronary events in patients with no previous CVD, but not in those with previous CVD (P = 0.03 for interaction).

There has been much conjecture concerning the conflicting results of FIELD. The degree of baseline dyslipidaemia [total cholesterol 5.0 mmol/L (195 mg/dL), total triglyceride 2.0 mmol/L (173 mg/dL), LDL cholesterol 3.1 mmol/L (119 mg/dL), and HDL cholesterol 1.1 mmol/L (43 mg/dL)], was possibly insufficient to demonstrate the optimal effect of the drug. In the Veterans Administration HDL Trial, a secondary prevention trial which demonstrated a positive outcome with gemfibrozil, baseline HDL cholesterol was 0.8 mmol/L. Other possible confounders include the higher drop-in therapy with statins in the placebo group, the potentially adverse effect of fenofibrate on homocysteine levels (an increase of 3.7 μmol/L) and the relatively small impact in reducing LDL cholesterol and increasing HDL cholesterol (only 2% by the end of the study). However, the major conclusion following the results of FIELD trial is that guidance on treatment strategies remains unchanged and statins remain the major treatment choice in the majority of diabetic patients.

Guidelines for HDL cholesterol and triglycerides
Given the paucity of information available from controlled trials, guidelines are less specific with regard to goals for HDL cholesterol and triglycerides. However, the joint European guidelines recognize low HDL cholesterol [<1 mmol/L (39 mg/dL) in men and <1.2 mmol/L (46 mg/dL) in women] and fasting triglycerides >1.7 mmol/L (151 mg/dL) as markers of increased vascular risk. In the recent update of ATP III for patients considered at very high risk, such as diabetic patients with symptomatic vascular disease, and high triglyceride and low HDL cholesterol consideration can be given to combining a fibrate or nicotinic acid with an LDL-lowering drug.348 When triglycerides are >2.3 mmol/L (>189 mg/dL) but LDL cholesterol levels are to goal following statin therapy, a secondary treatment target of non-HDL cholesterol (total cholesterol minus HDL cholesterol) is suggested with a goal 0.8 mmol/L (31 mg/dL) higher than the identified LDL cholesterol goal.

Recommendation
In diabetic patients with hypertriglyceridaemia >2 mmol/L (177 mg/dL) remaining after having reached the LDL-cholesterol target, it is recommended that statin therapy should be increased to reduce non-HDL cholesterol with a goal of therapy 0.8 mmol/L (31 mg/dL) higher than that identified for LDL. In patients on maximum dose, or maximum tolerated dose of statin, where LDL-C or non-HDL-C is not to goal, the addition of ezetimibe, a specific inhibitor of cholesterol absorption, should provide effective further cholesterol reduction. In some cases combination therapy with nicotinic acid, or fibrates may be considered. Class IIb, Level of Evidence B.

Future views
Diabetic dyslipidaemia is an important CVD risk factor that is open to therapeutic intervention. Much information is now available from RCTs to guide clinical practice, particularly with statins. On-going trials will provide further information concerning the added benefit of lowering LDL-cholesterol to levels below current guidelines. However, it seems reasonable, given the very high risk of diabetic patients with established CVD, that the new lower target of <1.8 mmol/L (<70 mg/dL) LDL suggested by ATP III should be adopted. For primary prevention, the new guidelines from the ADA, produced after the publication of HPS and CARDs, suggesting statin therapy regardless of baseline LDL to achieve a 30–40% reduction, is reasonable.

The on-going ACCORD Trial, will provide evidence for statin/fibrate combination in diabetes. Another statin combination, for instance with nicotinic acid, which has proved successful in atheroma regression trials, is likely to be considered given the HDL-increasing properties of nicotinic acid at doses less likely to impair insulin resistance. In the longer term, specific HDL-increasing drugs will
enable the HDL hypothesis to be tested in formal randomized clinical trials.

*Class of recommendation.  
*Level of evidence.

Background

Hypertension is up to three times more common in patients with type 2 DM than in non-diabetic subjects, and is frequent in patients with type 1 diabetes as well. In the latter condition, nephropathy usually precedes hypertension, which then accelerates the progress of micro- and macrovascular complications. Obesity, increasing age, and onset of renal disease further increase the prevalence of hypertension in diabetic patients.

Diabetes and hypertension are additive risk factors for atherosclerosis and CVD, and hypertension enhances the risk for such disease, more in patients with diabetes than in hypertensive normoglycaemic subjects, as demonstrated for instance by the Multiple Risk Factor Intervention Trial and the PROSpective Cardiovascular Munster (PROCAM) Study. There are several possible reasons for this increased risk, one being enhanced susceptibility to pressure-induced vascular wall stress. The diabetic myocardium may also be more sensitive to other risk factors for CVD, increasing the risk for myocardial hypertrophy, ischaemia, and heart failure. Furthermore, diabetic nephropathy is incrementally accelerated by a raised blood pressure creating a vicious cycle once hypertension and nephropathy are present. It should be noted that renal artery stenosis may be responsible for both renal insufficiency and hypertension in the diabetic patient. Screening for this condition is warranted in patients with refractory hypertension and/or renal insufficiency.

**Treatment targets**

Measures to lower raised blood pressure should be particularly aggressive in patients with either type 1 and type 2 diabetes, because of the substantially enhanced cardiovascular risk associated with increasing blood pressure levels. The UKPDS and the Hypertension Optimal Treatment (HOT) Study revealed that an intensive blood pressure-lowering treatment strategy is associated with a lower incidence of cardiovascular complications in patients with diabetes. Various manifestations of CVD, including stroke and renal disease, were markedly reduced in diabetic patients randomized to rigorous blood pressure control in comparison with those randomized to a less tight control. There is a general consensus that recommended blood pressure targets should be lower in patients with (<130/80 mm Hg) than in those without diabetes (<140/90 mm Hg). If tolerated, diabetic patients with nephropathy should be treated towards even lower blood pressure levels. A vigorous lowering of blood pressure may initially elevate serum creatinine, but will benefit renal function in a long-term perspective.

**Recommendation**

In patients with diabetes and hypertension, the recommended target for blood pressure control is <130/80 mm Hg. Class I, Level of Evidence B.

**How should blood pressure be lowered?**

As already outlined in these guidelines, life style interventions treatment should form the basis in the treatment of all patients with hypertension (see section on life style and comprehensive management). Although important, life style-oriented changes are usually insufficient for adequate blood pressure control. Most patients need some form of pharmacological treatment, and a combination of several blood pressure-lowering drugs is frequently needed to achieve satisfactory blood pressure control. Registries and clinical trials reveal that many patients with diabetes still do not reach the recommended target of a blood pressure <130 mm Hg systolic and <80 mm Hg diastolic. Thus, there is a considerable potential for improved patient management in this respect. Only a few large prospective, randomized clinical trials with anti-hypertensive agents have specifically been oriented towards patients with diabetes. However, several large placebo-controlled trials with sizeable subgroups of patients with diabetes have reported specifically on the outcome in that subgroup (Table 15). A consistent finding in these analyses is a marked reduction of the risk for subsequent cardiovascular events among patients on active treatment compared to those on placebo. This finding is consistent for all types of blood pressure-lowering drugs that have been studied.

Chosen as the initial drug, the beneficial effect of diuretics, beta-blockers (BB), calcium channel blockers (CCB), and ACE-inhibitors are well documented. More recently, different anti-hypertensive drugs have been compared to each other (Table 16). In some of these studies, it appears that blockade of the renin-angiotensin-aldosterone system seems to be of particular value, especially when treating hypertension in patients with diabetes at particularly high cardiovascular risk. Recent evidence supports the efficacy of an ACE-inhibitor rather than a CCB as initial therapy, when the intention is to prevent or retard the occurrence of microalbuminuria in hypertensive patients with diabetes. In the Losartan Intervention For Endpoint reduction in hypertension...
Study (LIFE), recruiting patients at high risk due to established LV hypertrophy, blood pressure-lowering therapy initiated with the angiotensin receptor blocker (ARB), losartan, was more effective in reducing the primary composite cardiovascular endpoint than the selective BB atenolol. In this study, the beneficial effect of losartan was even more apparent in the diabetic subpopulation, with a statistically significant difference also in all-cause mortality. It should be noted that the vast majority of patients in both groups received hydrochlorothiazide in addition to the ARB or BB.

As outlined in Table 15, the absolute risk reduction (ARR) caused by treatment of hypertension in patients with diabetes is consistently greater than in those without. The main aim when treating hypertension in diabetic patients is, therefore, to reduce blood pressure, whereas it seems less important by means of which drug or combination of drugs this is accomplished. An inhibitor of the renin–angiotensin–aldosterone system should, however, be part of the pharmacological combination. It is important to monitor renal function when instituting an ACE-inhibitor or an ARB, especially considering the risk of deterioration of renal function in the presence of renal artery stenosis.

A matter that has been intensively discussed over the last decades is whether the metabolic actions of various blood pressure-lowering drugs are important for long-term cardiovascular outcome. It is well established that the use of thiazides and BBs are associated with an increased risk of developing type 2 diabetes as compared to treatment with CCBs and inhibitors of the renin–angiotensin–aldosterone system. It is, however, not known whether treatment with BBs and/or thiazides in patients with established type 2 diabetes has any metabolic adverse events of clinical importance, including an increased risk for cardiovascular events. In the Anti-hypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), the outcome was similar in subgroups treated with a diuretic, an ACE-inhibitor, or a CCB. However, in that study, the subgroup of patients with IFG was very small in comparison with the diabetic and normoglycaemic subgroups. Thus, while drugs with negative metabolic effects, especially the combination of a thiazide and a BB, probably should be avoided as first line treatment when managing hypertensive patients with the metabolic syndrome, the goal of lowering blood pressure seems more important than minor alterations in the metabolic condition in patients with established diabetes. A recent observation, of potential interest in explaining differences between atenolol/thiazide-based, compared with amlodipine/perindopril-based, blood pressure-lowering therapy was
recently suggested in a substudy to ASCOT.\textsuperscript{155} The BB/thiazide-based treatment did not lower central blood pressure to the same extent as the other combination of drugs. It was proposed, that this may relate to a diminished cardiovascular protection of the former drug combination.

**Recommendation**
The cardiovascular risk in patients with diabetes and hypertension is substantially enhanced. The risk can be effectively reduced by blood pressure-lowering treatment. Class I, Level of Evidence A.

The diabetic patient usually requires a combination of several anti-hypertensive drugs for satisfactory blood pressure control. Class I, Level of Evidence A.

The diabetic patient should be prescribed a RAS inhibitor as part of the blood pressure-lowering treatment. Class I, Level of Evidence A.

Screening for microalbuminuria and adequate blood pressure-lowering therapy including the use of ACE-inhibitors and angiotensin receptor-II-blockers, improves micro- and macrovascular morbidity in type 1 and type 2 diabetes. Class I, Level of Evidence A.

**Epidemiology**

**Diabetes and ACS**

Diabetes is common among patients with ACS, whether diagnosed as AMI or unstable angina pectoris (UAP). In the Swedish Registry for Coronary Care, about 21% of patients with AMI are recorded as having known diabetes.\textsuperscript{388} The corresponding proportion ranges from 19 to 23% in the recent GRACE, OASIS, and EHS-ACS multinational registries.\textsuperscript{389–391} When patients with AMI, but without known diabetes, were challenged with an OGTT, 65% had an abnormal glucose regulation (previously undiagnosed diabetes = 25% and IGT = 40%), a much higher proportion than among age- and gender-matched healthy controls, among whom 65% had a normal glucose regulation (NGR).\textsuperscript{392,393} The prevalence of previously known and newly recognized diabetes based on fasting hyperglycaemia reached 28% in the EUROASPIRE II population.\textsuperscript{394} The Euro Heart Survey on Diabetes and the Heart, recruiting patients from 25 countries, disclosed unrecognized diabetes in 22% of patients acutely admitted for CAD when applying an OGTT, according to WHO.\textsuperscript{395} Based on these data, the overall proportion of DM among patients with ACS was estimated to be about 45%.\textsuperscript{396}

As has been described earlier (see section on Identification of subjects at high risk for CVD and diabetes), the prevalence of DM is increasing rapidly in the general population. Accordingly, it may be foreseen that diabetes will have a substantial impact on future morbidity and mortality in patients with ACS and also on health care expenditure for such disease.

**Prognostic implications**

In-hospital and long-term mortality after MI has declined over the years. Unfortunately, patients with diabetes have not benefited from improvements in health care to the same extent as those without this disease. In fact, the relative impact of diabetes on cardiovascular mortality is unchanged or even increasing.\textsuperscript{106} Patients with previously known diabetes admitted with ACS, have higher in-hospital mortality (11.7, 6.3, and 3.9% in MI with and without ST-elevation and UAP, respectively), than patients without diabetes (6.4, 5.1, and 2.9%) included in the GRACE registries.\textsuperscript{389} This unfavourable prognosis has persisted over time and is also reflected in long term mortality, as outlined in Table 17 as reported by studies performed at different periods of time and inspite of the introduction of improved treatment options.\textsuperscript{388,391,397–406}

Diabetes is associated with high total mortality, accounting for 7–18% at 30 days, 15–34% after 1 year, and up to 43% after 5 years.\textsuperscript{388,391,397–406} The relative risk for overall mortality, following adjustment for differences in baseline characteristics, concomitant diseases and baseline treatment, that is attributable to diabetes, varies between different studies, ranging from 1.3 to 5.4.\textsuperscript{391,397–406} This risk is somewhat higher among women than men.\textsuperscript{389} Patients with newly detected type 2 diabetes have similar proportions of re-infarction, stroke, and 1-year mortality following an AMI as patients with previously established diabetes.\textsuperscript{406}

The main complications in patients with ACS include recurrent myocardial ischaemia, LV dysfunction, symptomatic heart failure, electrical instability (ventricular fibrillation, ventricular tachycardia, atrio-ventricular block, and sudden cardiac death), cardiogenic shock, re-infarction,
stroke, or death. Most of these complications are significantly more common in patients with diabetes. Based on a cohort of more than 10,000 survivors of AMI, the GISSI prevention investigators identified 12 independent predictors of long-term mortality [relative risk (RR)]. The risk factors with the strongest negative influence on prognosis were age [65–69 years: males 2.1 (1.7–2.7), females 3.3 (1.4–7.9)]; LV dysfunction [males 2.0 (1.8–2.3), females 2.0 (1.5–2.8)]; intermittent claudication [males 1.6 (1.3–2.0), females 3.3 (1.9–5.8)]; continued smoking [males 1.5 (1.2–1.7), females 2.5 (1.4–4.4)], and diabetes [males 1.3 (1.1–1.5), females 1.9 (1.4–2.7)].

Generalized atherosclerosis is common in type 2 diabetes; clinically manifested peripheral artery disease is three to four times more common and the incidence of cerebrovascular disease about doubled, as can be noted reviewing the baseline characteristics of patients included in various studies. The markedly increased adjusted risk of death associated with diabetes beyond the acute phase of coronary events indicates the profound role of the gluco-metabolic derangement. Dysglycaemia at any level causes alterations in energy substrate metabolism, including insulin resistance, increased concentrations of non-esterified fatty acids, and excessive oxidative stress. These metabolic factors are further enhanced at the onset of an AMI, when chest pain, breathlessness, and anxiety cause a stress-induced increase in adrenergic tone. As outlined more in detail in the pathophysiology chapter, diabetic patients often have a widespread and diffuse CAD, decreased vasodilatory reserve, decreased fibrinolytic activity, elevated platelet aggregability, autonomic dysfunction, and possibly diabetic cardiomyopathy, all factors to be taken into account when choosing therapy. Impaired glucose control may operate in the long-term as well. In type 2 diabetes, metabolic control measured as fasting blood glucose or glycated haemoglobin (HbA1c) is a major risk factor for future CHD. Furthermore, a high blood glucose level at admission is a powerful predictor for in-hospital and long-term mortality, both in patients with and without DM.

Heart failure is a common complication in survivors of an acute coronary event occurring with almost a linear time-dependent proportion (1.3% yearly) with almost 5% in the first week and 6.3% after 6 months. The incidence of heart failure is a strong predictor of subsequent mortality, markedly increasing the risk up to 10-fold, as reported in the most recent publications from the OASIS-2 and Cholesterol and Recurrent Events Substudy (CARE) studies.

### Treatment principles

**Revascularization**

Studies on accurately characterized diabetic patients with CVD, including precise information on how the condition was diagnosed and treated, are limited. Prospective randomized, large clinical trials usually recruited low numbers of patients with diabetes due to exclusion and inclusion criteria and studies on pure diabetic populations are sparse. Thus, most information on the treatment of diabetic patients with ACS is derived from retrospective subgroup analyses and patient registries. Several registry studies show that diabetic patients are not as well-treated as non-diabetic patients, with regard to evidence-based therapy and coronary interventions. In particular, it seems that heparins, thrombolytic agents, and coronary interventions are less frequently administered. One explanation may, as a consequence of autonomic neuropathy, be lack of typical symptoms in diabetic patients with coronary ischaemia. The reported prevalence of silent ischaemia is 10–20% in diabetic, compared with 1–4% in non-diabetic populations. Accordingly, silent infarctions or infarctions with atypical symptoms are more common in diabetic patients, prolonging time to hospital admission as well as to diagnosis, thereby reducing the opportunity to administer adequate treatment. Another possible reason is that the diabetic patient is considered more vulnerable and that this disease has been experienced as a relative contraindication to some of these treatment modalities. Nevertheless, evidence-based coronary care treatment, including early coronary angiography and, if possible, revascularization, is at least as effective in the diabetic patient as in the non-diabetic patient and there are no indications for an increased propensity to side-effects, as shown in some recent studies.

### Risk stratification

Patients with ACS and concomitant DM, already known or newly recognized, are at high risk for subsequent complications. An extended risk assessment is important to identify specific threats and outline goals for the long-term management strategy. Early risk assessment is recommended, in order to identify possible co-morbidities and factors increasing the cardiovascular risk. This includes: (i) a thorough evaluation of history and signs of peripheral, renal, and cerebrovascular disease; (ii) a careful evaluation of such risk factors as blood lipids, blood pressure, and of smoking and life style habits; (iii) clinical risk predictors including heart failure, hypertension, and risk for arrhythmia, with special focus on autonomic dysfunction; (iv) investigations of inducible ischaemia by means of ST-segment monitoring, exercise testing, stress echocardiography, or myocardial scintigraphy (whatever method is appropriate for the individual patient and clinical setting); (v) assessment of myocardial viability and LV function by means of echo-Doppler and/or magnetic resonance imaging. The reliability (sensitivity/specificity) of exercise testing, stress echocardiography, or myocardial scintigraphy is of a particular concern for detection of ischaemia in diabetic patients. Confounders are a potentially high threshold for pain due to autonomic dysfunction, the multivessel nature of the coronary disease, baseline electrocardiographic abnormalities, a commonly poor exercise performance of diabetic patients, coexistence of peripheral artery disease, and use of multiple medications. In this context, a careful clinical evaluation and focused evaluation of laboratory outcomes are of particular importance.

### Recommendation

Early risk stratification should be part of the evaluation of the diabetic patient after ACS. Class IIa, Level of Evidence C.

### Treatment targets

The management of diabetic patients following ACS aims at preventing further events, i.e. death, recurrent MI, progression to irreversible myocardial damage, or other cardiovascular events. Available treatment options, meant to preserve

ACS = acute coronary syndromes; UAP = unstable angina pectoris; NA = not available; RCT = randomized controlled trial; SK = streptokinase; DM = diabetes mellitus; HF = heart failure; F = females; M = males; m = months

\textsuperscript{a}5-year mortality rates for survivors over 28 days.
and optimize myocardial function, achieve stabilization of vulnerable plaques, prevent recurrent events by controlling prothrombotic activity, and to counteract progression of atherosclerotic lesions are summarized in Table 18.\(^{417,418}\)

Evidence-based recommendation for secondary prevention is in general terms valid for patients with, as well as without, diabetes. Since diabetes is associated with consistently higher absolute risk for cardiovascular morbidity and mortality, the management strategy should, if anything, be even more ambitious in this category of patients. For an equal risk reduction, the number of patients needed to treat to save one life or prevent one defined endpoint is lower among diabetic patients due to the higher absolute risk. Important treatment targets are outlined in Table 19, summarizing recommendations for secondary prevention, based on accumulated evidence, including data from recent guidelines and consensus documents.\(^{130,419-421}\)

**Recommendation**

Treatment targets, as listed in Table 19, should be outlined and applied in each diabetic patient following an ACS. Class IIa, Level of Evidence C.

**Specific treatment**

**Thrombolysis**

The most important goal of treatment in AMI is to restore patency in the compromised coronary artery. This can either be done with thrombolytic drugs or by mechanical intervention. Thrombolysis is at least as beneficial in diabetic as in non-diabetic patients. A meta-analysis of 43 343 MI patients, 10% of whom had a history of diabetes, revealed that the number of lives saved by thrombolytic therapy was 37 per 1000 treated patients in the diabetic cohort, compared with 15 among those without DM.\(^{422}\) Thus, due to their higher risk, fewer numbers are needed to treat to save one life in the diabetic cohort, corresponding to a greater absolute benefit for thrombolytic treatment in diabetics than in non-diabetic patients. It is a myth that thrombolysis is contraindicated in diabetic patients due to an increased risk of eye or cerebral bleeding.

**Recommendation**

Patients with AMI and diabetes should be considered for thrombolytic therapy on the same grounds as their non-diabetic counterparts. Class IIa, Level of Evidence A.

**Early revascularization**

Revascularization is undertaken to counteract myocardial ischaemia, protect viable myocardium, and prevent progression to MI or death. The choice between percutaneous coronary intervention (PCI) and coronary artery bypass grafting (CABG) is discussed further in this chapter.

A recent meta-analysis of randomized trials including patients with non-ST-elevation myocardial infarction (NSTEMI) and unstable angina, revealed that an early invasive strategy, including coronary angiography followed by coronary revascularization, reduced mortality from 4.9 to 3.8% (OR 0.76; CI: 0.62–0.94), the composite of death or MI from 11.0 to 7.4% (OR 0.64; CI 0.56–0.75), and resulted in a 33% reduction of severe angina and re-hospitalizations during an average follow-up of 17 months, when compared to a strategy with an invasive approach only in case of inducible ischaemia or recurrent symptoms.\(^ {423}\)

Revascularization within 14 days following an AMI, ST-elevation as well as non-ST-elevation, caused a 53% reduction in 1-year mortality in patients without and 64%

---

### Table 19 Recommended treatment targets for patients with diabetes and CAD (adapted after the European Guidelines for Cardiovascular Disease Prevention)\(^ {419}\)

| Blood pressure (systolic/diastolic; mm Hg) | <130/80 in case of renal impairment, <125/75 |
| Glycaemic control | HbA\(_1c\) (%)\(^a\) | <6.5 |
| Glucose expressed as venous plasma mmol/L (mg/dL) | Fasting | <6.0 (108) |
| Post-prandial (peak) | <7.5 (135) diabetes type 2 |
| <7.5–9.0 (135–160) diabetes type 1 |
| Lipid profile expressed in mmol/L (mg/dL) | Total cholesterol | <4.5 (175) |
| LDL-cholesterol | <1.8 (70) |
| HDL-cholesterol | Men | >1.0 (40) |
| | Women | >1.2 (<46) |
| Triglycerides\(^b\) | <1.7 (<150) |
| TC/HDL\(^b\) | <3 |
| Smoking cessation | Obligatory |
| Regular physical activity (min/day) | >30–45 |
| Weight control | BMI (kg/m\(^2\)) | <25 |
| In case of overweight weight reduction (%) | 10 |
| Waist (optimum; ethnic specific; cm) | Men | <94 |
| | Women | <80 |
| Dietary habits | Salt intake (g/day) | <6 |
| Fat intake (% of dietary energy) | Saturated | <10 |
| Trans fat | <2 |
| Polyunsaturated n-6 | 4–8 |
| Polyunsaturated n-3 | 2 g/day of linolenic acid and 200 mg/day of very long chain fatty acid |

\(^a\)DCCT-standardized, for recalculation formula for some national standards in Europe.\(^ {156}\)

\(^b\)Not recommended for guiding treatment, but recommended for metabolic/risk assessment.
among those with diabetes (15 vs. 5%; RR 0.36; CI 0.22–0.61). The early invasive reperfusion strategy among diabetic patients with unstable angina or NSTEMI in the FRISC-II Trial resulted in significant reduction of the composite endpoint of death or myocardial re-infarction from 29.9–20.6% (OR 0.61; CI 0.36–0.54). The relative impact of the early invasive strategy was of the same magnitude in both diabetic and non-diabetic patients. This means that, due to the significantly higher absolute risk, the relative benefit was substantially larger in diabetic than in non-diabetic patients. The NNT to save one death or MI was 11 for diabetic and 32 in non-diabetic patients.

Recommendation
Whenever possible, patients with diabetes and ACS should be offered early angiography and mechanical revascularization. Class IIa, Level of Evidence B.

Anti-ischaemic medication
Beta-blockade
Post-myocardial treatment with beta-blockade results in a general mortality reduction, as reflected by a systematic overview of scientific reports published 1966–1997 by Freemantle et al. In this meta-analysis, the overall mortality reduction was 23% (CI 15–31%), which can be translated into a number of 42 patients needed to treat during 2 years to save one life. BBs are particularly effective in decreasing post-infarction mortality and new infarcts in patients with a history of DM.

Based on accumulated evidence of improved survival, prevention of re-infarction, and sudden cardiac death and reduction or treatment of late ventricular arrhythmias, oral BBs are, in the absence of contraindications, recommended for all diabetic patients with ACS. Furthermore, such patients are more prone to develop heart failure and recent trials have clearly documented the beneficial effects of beta-blockade in heart failure patients. Accordingly, although to a large extent based on subgroup analyses, a liberal use of BBs in diabetic patients with MI is advocated since the beneficial effects have a solid basis in pathophysiology. It seems reasonable to make individualized drug choices among different BBs bearing in mind concomitant conditions and type of diabetes treatment. Selective beta-1 antagonists may be prefered in case of insulin treatment and alfa-1-beta-adrenergic antagonists such as carvedilol may offer additional benefits for patients with peripheral artery disease or substantial insulin resistance. Still, contemporary data report that diabetic patients with CAD are deprived from this life-saving treatment. BBs should be used in adequate dosages as detailed in a recent expert consensus document on beta-adrenergic blockers.

Recommendation
BBs reduce morbidity and mortality in patients with diabetes and ACS. Class IIa, Level of Evidence B.

Other drugs
Nitrates and calcium antagonists belong to anti-ischaemic drugs. Recent meta-analyses do not reveal survival benefits for any of them, although favourable effects have been reported for diltiazem in patients with non-ST-elevation infarctions. Long-acting calcium channel antagonists and nitrates are therefore not generally recommended, but they may be of value for symptomatic relief in patients already treated with BBs or with contraindications for their use.

Anti-platelet and anti-thrombotic agents
Reducing platelet aggregation by acetylsalicylic acid therapy is a cheap and effective way to reduce mortality and morbidity in patients with CAD, not the least those with ACS. It has been claimed, but not verified, that diabetic patients need particularly high doses of aspirin for efficient suppression of platelet-derived thromboxane A2. A systematic analysis of 195 trials including more than 135 000 patients (4961 with diabetes) at high risk for arterial disease against antiplatelet therapy in the form of aspirin, clopidogrel, dipyridamol, and glycoprotein IIb/IIIa antagonists (separately or in combination) revealed that the risk of stroke, MI, or vascular death was reduced by about 25%. The benefits experienced among diabetic patients were somewhat lower. The anti-thrombotic trialists concluded that the optimal effective aspirin dose is 75–150 mg daily, with a loading dose of 150–300 mg to be introduced when an immediate effect is needed.

Recommendation
Aspirin should be given for the same indications and in similar dosages to diabetic and non-diabetic patients. Class II, Level of Evidence B.

When added to aspirin, the effect of thienopyridines (Ticlopidine, Clopidogrel), which block the adenosine diphosphate (ADP) receptor-dependent platelet activation, is favourable in patients with unstable angina and non-ST-elevation infarctions, lowering the incidence of cardiovascular death, MI, or stroke from 11.4 to 9.3%; (RR 0.80; CI 0.72–0.90). The outcome of the CURE Trial resulted in the recommendation to use clopidogrel (75 mg daily) combined with aspirin (75–100 mg daily) to be continued for 9–12 months following an acute coronary event. Among patients with diabetes and vascular disease, clopidogrel provides better protection from serious events (vascular death, re-infarctions, stroke, or recurrent hospitalization for ischaemia) than aspirin (RR 0.87; CI 0.77–0.88; CAPRIE).

Recommendation
ADP receptor-dependent platelet activation (clopidogrel) should be considered in diabetic patients with ACS in addition to aspirin. Class IIa, Level of Evidence C.

ACE-inhibitors
Blockers of the RAS (ACE-inhibitors) have not been shown to offer any particular advantage in diabetic compared with non-diabetic patients in connection to an MI, except from a report from the GISSI-3 Trial. In a subgroup analysis from this study, early institution of lisinopril reduced mortality in patients with diabetes, however, not in their non-diabetic counterparts. The possibility that the ACE-inhibitor ramipril may prevent cardiovascular events in people with diabetes was tested in the Heart Outcomes Prevention Evaluation (HOPE) Study. A total of 3654 patients with diabetes and previous CVD or one or more risk factors for such disease were recruited to a subgroup in which diabetes was a pre-specified study question. There was a 25% reduction in the composite endpoint of MI, stroke, or...
cardiovascular death, and a clear reduction in each of the component outcomes. More recently, the European Trial on Reduction Of cardiac events with Perindopril in stable CAD (EUROPA) Study extended these findings to a population that in absolute terms had at lower cardiovascular risk than in HOPE. Reduction of cardiovascular morbidity and mortality with perindopril was observed irrespective of a relatively high use of other secondary prevention therapies. The proportionate benefit for patients with diabetes was similar to those in the overall population. The absolute benefit was, however, greater because of the higher event rate among diabetic subjects.432,443

Due to hypertension, more than 50% of patients with type 2 diabetes are exposed to a considerably increased cardiovascular risk. Strict control of the elevated blood pressure is an effective secondary preventive measure in these patients. Details on blood pressure control and the use of various drugs, including ACE-inhibitors, alone or in combination, is given elsewhere in these guidelines (see section on hypertension).

**Recommendation**

The addition of an ACE-inhibitor to other effective therapies reduces the risk for cardiovascular events in patients with diabetes and established cardiovascular disease. Class I, Level of Evidence A.

**Lipid-lowering drugs**

The use of lipid-lowering therapy is discussed in a separate chapter of these guidelines (see section on dyslipidemia).

**Metabolic support and control**

There are several reasons why intensive metabolic control during an AMI should be of benefit. It would direct myocardial metabolism from beta-oxidation of FFA towards less energy consuming glucose utilization. One way to achieve this effect is to infuse insulin and glucose. Intense insulin-based glucose control treatment also has the potential to improve platelet function, correct the disturbed lipoprotein pattern, and decrease PAI-1 activity, thereby improving spontaneous fibrinolysis (see section on pathophysiology). The concept of acute and/or chronic metabolic control was tested in the two DIGAMI trials. DIGAMI 1 recruited 620 patients with diabetes and AMI to be randomly assigned to serve as a control group or to a group receiving intensive insulin treatment, initiated by an insulin–glucose infusion during the first 24 h after MI.323 One-year mortality was reduced by 30% in the intensively treated group, and this therapy tended to favourably influence all cardiovascular causes of death.325 In a long-term follow-up over an average of 3.4 years, there was an 11% absolute mortality reduction in the group subjected to intensive insulin treatment, implying one saved life for every nine patients treated.469 Of particular interest was that patients without previous insulin treatment and at a relatively low risk benefited the most. HbA1c, used as the measure of improved metabolic control, decreased on an average by 1.4% in this group of patients. An interesting finding was that the well-established epidemiological relationship between admission glucose level and mortality was only seen among the control patients, indicating that proper metabolic treatment in the peri-infarction period attenuated the harmful effect of a high blood glucose level on admission.322

The second DIGAMI Trial compared the three management protocols: acute insulin–glucose infusion followed by insulin-based long-term glucose control; insulin–glucose infusion, followed by standard glucose control; routine metabolic management according to local practice, in 1253 patients with type 2 diabetes and suspected AMI.326 The DIGAMI 2 Trial did not show that an acutely introduced, long-term intensive insulin treatment strategy improves survival in type 2 diabetic patients following MI and did not demonstrate that initiating treatment with an insulin–glucose infusion is superior to conventional management. The overall mortality in DIGAMI 2 was, however, lower than expected. Moreover, glucose control was better than in DIGAMI 1 already at the onset of treatment and the three glucose management strategies did not result in a significantly different glucose control. Indeed, target glucose levels were not reached in the intensive insulin group and were better than expected in the two other arms. Blood glucose was fairly well controlled in DIGAMI 2 even if the targeted levels could not be reached in the insulin arm. Given a similar degree of glucose regulation, it seemed as if insulin per se did not improve the prognosis more than any other combination of glucose-lowering drugs. The DIGAMI 2 Trial clearly confirmed that glucose level is a strong, independent predictor of long-term mortality following MI in patients with type 2 diabetes, with a 20% increase in long-term mortality for an increase in updated plasma glucose by 3 mmol/L.

A meta-analysis of several early studies on glucose–insulin–potassium (GIK) therapy in AMI, including 1932 predominantly non-diabetic patients, suggested a proportional acute mortality reduction of 28%. The treatment effect was further enhanced if only studies utilizing high-dose intravenous GIK regimens were taken into consideration.410 In the Estudios Cardiologicos Latinoamerica (ECLA) Trial, involving 400 patients, there was a trend towards a non-significant reduction in major and minor in-hospital events in patients allocated to GIK therapy. However, in a subgroup comprising 252 patients who also had reperfusion therapy, there was a significant reduction in mortality in the treated group compared with the controls.411 The recent CREATE-ECLA Trial randomized more than 20 000 patients with acute ST-elevation infarction, out of whom 18% had type 2 diabetes, to high dose GIK or to standard care. This included acute reperfusion therapy in more than 80% of the patients. The overall outcome of this large-scale study was that GIK did not influence mortality, cardiac arrest, or cardiogenic shock.444 It must be emphasized that none of these trials targeted a pure diabetic population or aimed at normalization of blood glucose per se. In fact, there was a significant increase in blood glucose levels in the CREATE-ECLA Trial, which may have contributed to the neutral result. The very consistent results from this trial strongly suggest that acute metabolic intervention by means of GIK has no place in the contemporary treatment of patients with AMI, if not used to normalize blood glucose.

In contrast, and as discussed in detail elsewhere in these guidelines (see section on intensive care), a Belgian surgical ICU Study which targeted a ‘normal’ glucose level (4.5–6.1 mmol/L; 80–110 mg/dL) in the actively treated group showed a significant decrease in mortality and also infection rate, compared with the conventional treated group.445
Based on present knowledge, there is reasonable evidence to initiate glucose control by means of insulin infusion in diabetic patients who are admitted for AMIs with significantly elevated blood glucose levels in order to reach normoglycaemia as soon as possible. Patients admitted with relatively normal glucose levels may be handled with oral glucose-lowering agents. In the follow-up, both epidemiological data and recent trials support that continued strict glucose control is beneficial. The therapeutic regime to accomplish this goal may include diet, life styles strategies, oral agents, and insulin (see also section on life style and comprehensive management). Since there is no definite answer to which pharmacological treatment is the best choice, the final decision can be based on decisions by the physician-in-charge in collaboration with the patient. Most importantly, the effect on long-term glucose control has to be followed and the levels should be targeted to be as normal as possible. Several outcome studies with novel agents or regimens are ongoing and will report in the near future.

**Recommendation**

Diabetic patients with AMI benefit from tight glucometabolic control. This may be accomplished by different treatment strategies. Class IIa, Level of Evidence B.

### A comprehensive therapeutic strategy

Effective management of diabetic patients during and after acute coronary events is demanding, as the reduction of several risk factors including blood glucose must be achieved for satisfactory results. An aggressive multi-disciplinary and multi-factorial therapeutic strategy is, however, beneficial. In the STENO 2 Study, such approach halved the risk of cardiovascular events in diabetic patients at high risk verified by concomitant microalbuminuria. In the second DIGAMI Trial, aggressive treatment from the early onset of MI was the probable reason for the unexpectedly low, 18%, 2-year mortality, an outcome approaching that of non-diabetic patients. The effectiveness of PCI and bypass surgery as a mode of revascularization has been compared in several RCTs, among them the Bypass Angioplasty Revascularization Investigation (BARI), Coronary Angioplasty vs. Bypass Revascularization Investigation (CABRI), Emory Angioplasty vs. Surgery Trial (EAST), and Randomized Intervention Treatment of Angina (RITA).

### Diabetes and coronary revascularization

Revascularization of narrowed or occluded coronary vessels by means of CABG was first introduced by thoracic surgeons in 1964. The less invasive revascularization modality, PCI, was introduced in 1977, rapidly growing to a new field in cardiology. Many diabetic patients, who were previously considered candidates for surgery, have been successfully treated by PCI, with good long-term results. Revascularization procedures may be indicated in diabetic patients with stable or unstable coronary syndromes, covering the whole spectrum of ischaemic heart disease from asymptomatic patients to ST-elevation MI, ACS, and resuscitated sudden cardiac death. Patients with diabetes have a higher mortality and morbidity after CABG compared with non-diabetics, but this is also seen in patients undergoing PCI. The influence of glucometabolic control on the outcome after revascularization (insulin vs. oral agents) is still unclear. Patients who require insulin have more adverse events, but this may be induced by a more advanced diabetes related morbidity, including atherosclerosis and/or microvascular disease, and perhaps also by so far unknown variables in these patients.

CABG in diabetic compared with non-diabetic patients results in lower short- and long-term survival and more complications, including increased incidence of mediastinitis and sternal wound infections and delayed healing in general. Bilateral mammary artery grafting may be a risk factor for complications in the presence of diabetes, but internal mammary artery grafts also improve long-term outcome. Likewise, diabetic patients undergoing PCIs have a lower survival than their non-diabetic counterparts. They are at increased risk for adverse short- and long-term outcomes, including a higher need for in-hospital CABG, and a higher incidence of stent thrombosis, restenosis, demand of repeat revascularization and MI.

### Surgery vs. percutaneous intervention

The effectiveness of PCI and bypass surgery as a mode of revascularization has been compared in several RCTs, among them the Bypass Angioplasty Revascularization Investigation (BARI), Coronary Angioplasty vs. Bypass Revascularization Investigation (CABRI), Emory Angioplasty vs. Surgery Trial (EAST), and Randomized Intervention Treatment of Angina (RITA).

In these studies, balloon angioplasty was applied as a mode of PCI and no coronary stents were used. Later, when stents became available, studies were conducted, comparing this new percutaneous technology with CABG in multivessel CAD. Major concerns were raised when a post-hoc subgroup analysis of BARI patients with diabetes and multivessel disease demonstrated a less favourable prognosis among those treated with PCI than those subjected to CABG (Table 20).

In BARI, the 7-year survival for the total population was 84.4% for surgically treated patients and 80.9% for PCI ($P = 0.043$). The corresponding proportions for diabetes patients were 76.4% vs. 55.7% ($P = 0.001$).

This suggests that the non-significant treatment difference between the two groups was limited to the PCI patients with diabetes. Furthermore, in BARI, the survival difference...
was in fact also limited to those diabetic patients who received at least one arterial internal mammary graft.459 These grafts are known to provide better long-term patency than saphenous vein grafts. BARI was not designed to focus on diabetic patients. The suspicion raised by BARI, that long-term prognosis after PCI might be worse in patients with diabetes with multivessel disease, was, however, confirmed by another large registry of consecutive revascularization procedures.479

Unrandomized patients, eligible for the BARI Study, were included in a registry. Their mode of revascularization was left to the discretion of patients and physicians. In this BARI-registry similar differences in mortality were not observed456,460 (Table 20). In addition, three other studies, conducted in the balloon angioplasty era, could not confirm the conclusion from BARI with regard to diabetic patients undergoing PCI: RITA-1, CABRI, and EAST (Table 20).471–473

The Angina with Extreme Serious Operative Mortality Evaluation (AWESOME) Trial randomized only patients with unstable angina and high surgical risk. A total of 54% of the patients in the PCI group received stents and 11% received glycoprotein IIb/IIIa antagonists.477 The combined impression from these studies is that survival does not differ, but that diabetic patients have a significantly higher incidence of repeat revascularization and that restenosis is still a major problem especially in this patient category (Tables 20 and 21).

Recommendation

Treatment decisions regarding revascularization in patients with diabetes should favor CABG surgery over percutaneous intervention. Class Ila, Level of Evidence A.

Whenever possible, patients with diabetes undergoing coronary bypass surgery should be offered at least one and often multiple arterial grafts. Class I, Level of Evidence C.

Adjunctive therapy

All studies mentioned still raise the question whether revascularization by means of PCI or CABG is to be preferred in patients with diabetes and multivessel disease.

Stents and later DES have been hailed to improve the outcome of PCIs in the diabetic patient. Although the results are promising, only one small study did in fact address subacute stent thrombosis, restenosis, and long-term outcome in this patient category, and other available data relate to subsets of patients included in studies on stents and DES.457,462,480–482 A recent meta-analysis comparing DES with bare metal stents in diabetic subpopulations in several clinical trials revealed that DES were associated with an 80% RRR for restenosis during the first year of follow-up.481 Future clinical trials comparing DES with coronary bypass surgery are certainly needed to determine the optimal revascularization strategy in diabetic patients with multivessel disease. Newer stents with improved design and especially new bare metal stents with thin struts have also been successful in decreasing the incidence of restenosis.481 However, definite conclusions with regard to treatment outcome can only be drawn from a randomized comparison of these newer stents with DES in well-defined patients with diabetes.

Potent platelet glycoprotein IIb/IIIa inhibitors improve the outcome after PCIs when administered during the procedure in diabetic patients. In three randomized trials with abciximab, there was a 44% reduction of mortality after 1 year, suggesting that these agents are indicated in all diabetic patients undergoing PCI.482 ADP receptor antagonists (thienopyridines), like clopidogrel, may prevent early as well as late thrombotic complications after stent implantation, particularly in patients with diabetes.438

Cardiac surgery has also witnessed major improvements over the past decade and new techniques like minimal invasive surgery, robot techniques, and off-pump procedures are promising with regard to short- and long-term outcome.484 A recent paper renewed the interest in differences in revascularization techniques in multivessel disease, but whether this also applies to diabetic patients remains uncertain.485,486

In patients with diabetes, the progressive nature of the atherosclerotic disease, the marked endothelial dysfunction, and platelet and coagulation abnormalities are responsible for a less favourable outcome after

ARTS, the Arterial Revascularization Therapy Study; SoS, the Stent or Surgery Trial.
Revascularization. Additional treatment should be focused on these specific disease entities, with special attention paid to concomitant disease and risk factors like hypertension, dyslipidaemia, smoking, and life style (see other parts of these guidelines). However, no randomized trials have been conducted to see whether these measures will affect the outcome after revascularization procedures. Results from randomized trials and registries may be used to treat patients with diabetes with ACE-inhibitors or BBs after revascularization, but no randomized data are available.472,456 Furthermore, no data are available regarding whether improved glycaemic control and pharmacological intervention can reduce the incidence of restenosis after PCI or improve patency of bypass grafts after CABG.487-489

Whether diabetes in general is associated with an increased physician’s preference for either medical or revascularization treatment was recently addressed in the Euro Heart Survey on coronary revascularization. In a broad range of European practices, diabetes was not among the factors that determine treatment decisions in stable coronary disease.490 However, the higher incidence of repeat revascularization in PCI-treated patients should always be taken into consideration. Although patients presenting with ACS have different clinical characteristics than those who present with stable coronary syndromes, the general opinion is that the approach with regard to the mode of revascularization has to be identical.491

Recommendation
Glycoprotein Iib/IIa inhibitors are indicated in elective PCI in patients with diabetes. Class I, Level of Evidence B.

When PCI with stent implantation is performed in patients with diabetes, DES should be used. Class IIa, Level of Evidence B.

Revascularization and reperfusion in MI
Patients with diabetes or hyperglycaemia may have a different response to several treatment strategies used for MI.400,492-494 In patients with ST-segment elevation MI, thrombolysis seems to be less effective in those with diabetes.495 In general, increasing evidence suggests that primary PCI is preferable to thrombolysis as reperfusion therapy for ST-segment elevation MI.496-498 Whether this benefit is present in patients with diabetes is less clear. Still, primary PCI has been suggested as the treatment of choice in high-risk patients, among whom are the diabetic patients.496,497 Although thrombolysis is less beneficial in diabetic patients, revascularization and reperfusion by primary PCI may also be less successful, due to more diffuse CAD, smaller reference diameters, and a tendency for higher restenosis rates.499,500 Patients with DM have an adverse prognosis after ST-segment elevation MI and myocardial reperfusion as assessed by ST-segment resolution and myocardial blush grade, demonstrating more frequently reduced blush and incomplete ST-segment resolution after primary angioplasty, compared with patients without diabetes.501

Identifying the optimal method of reperfusion in diabetic patients is of great clinical importance, as the number of ST-segment elevation MI patients with diabetes is high and their prognosis poor.395,501 A recent analysis of diabetic patients included in 11 randomized trials demonstrated a survival benefit for those treated with primary PCIs over those with thrombolytic treatment.497,498 These findings have been confirmed by two other studies.502,503

Cardiac surgery in the setting of ST-segment elevation MI is only indicated when the coronary anatomy is not suitable for a percutaneous intervention, after such intervention has failed and the area of myocardium at risk is large, or when mechanical complications occur.

Recommendation
Mechanical reperfusion by means of primary PCI is the revascularization mode of choice in diabetic patients with AMI. Class I, Level of Evidence A.

Unresolved issues
In patients with diabetes and CAD, both PCIs and CABG are treatment options, although it remains to be determined if one is preferable over the other. Reperfusion and revascularization in diabetic patients with ST-segment elevation MI should probably be accomplished by means of primary PCIs to ensure optimal reperfusion of the epicardial vessel, as well as on the level of the myocardial tissue.

Many previous randomized trials addressing these issues were performed before the current era of modern stent technology and new pharmacologic adjunctive therapy. Furthermore, the vast majority of studies only includes subgroups of patients with diabetes and was not dedicated to patients with diabetes in particular. Only new controlled randomized trials applying modern revascularization technology in patients with diabetes will give the answer whether CABG, hybrid revascularization procedures, or PCIs is the preferred treatment modality in these patients. Diffuseness of atherosclerotic involvement, type of diabetes, suitability for percutaneous intervention, clinical presentation, presence of chronic total occlusion, lesion morphology and involvement of proximal left anterior descending coronary artery, co-morbidity, and other factors may define subgroups that may benefit specifically from one or the other revascularization option. Other conditions like LV function, valvular abnormalities, and age may also be of crucial importance in making decisions.

In the Future Revascularization Evaluation in Patients with Diabetes Mellitus: Optimal Management of Multivessel Disease (FREEDOM) Trial, patients with diabetes will be randomized for CABG or PCIs with sirolimus-coated DES with the composite of death, MI, and repeat revascularization as the primary endpoint.504 The Bypass Angioplasty Revascularization Investigation II-Diabetes (BARI-IIID) Trial will enrol patients for PCIs or CABG and different regimens of optimal medical management, whereas the Coronary Artery Revascularization in diabetes Trial (CARDia) will enrol 600 diabetic patients to compare PCIs and CABG on a non-inferiority design base.505 The 1500-patient, prospective, multicentre, multinational (European and North American), randomized SYNTAX Study506 will enrol consecutive patients with de novo three-vessel disease and/or left main disease, randomizing patients for PCIs or CABG. Randomized patients will further be stratified on presence of diabetes. The primary endpoint...
for this comparison is non-inferiority of major adverse cardiac and cerebral events between the two groups at 1 year. Until such trials addressing the key issues in revascularization in diabetic patients have been completed, an indicative classification is highly speculative.

aClass of recommendation.  
bLevel of evidence.

Background

According to the guidelines issued by the ESC, the diagnosis of heart failure should be based on a combination of clinical symptoms of heart failure and signs of myocardial dysfunction. In clinical practice, heart failure is commonly divided into systolic dysfunction, representing an impaired capacity to eject blood from the left ventricle and diastolic dysfunction, an impaired ventricular filling due to relaxation abnormalities.506

Echocardiography is the preferred method for documentation of cardiac dysfunction and the most important measurement for diagnosing impaired systolic dysfunction is the LV ejection fraction (EF). Evidence of abnormal LV relaxation, diastolic distensibility, or diastolic stiffness are echocardiographic signs of diastolic dysfunction diagnosed in the presence of normal or mildly abnormal LV systolic function.506 Echocardiography, including Tissue Doppler Imaging is useful in detecting myocardial dysfunction in diabetic patients, as well as, in the non-diabetic population.507 Plasma concentrations of natriuretic peptides or their precursors may also be helpful for diagnosing heart failure in diabetic patients.506,508

The leading causes of chronic heart failure are hypertension and ischaemic heart disease.506,509 Other common factors influencing the occurrence of this syndrome are smoking, overweight, physical inactivity, and type 2 diabetes, as well as, poor glucometabolic control observed as high FPG and elevated HbA1c.296,510–513

Epidemiological aspects

Prevalence of heart failure and glucose abnormalities

The prevalence of heart failure varies somewhat in different studies. The prevalence of heart failure has been estimated to be 0.6–6.2% in Swedish men and this increases with age. This is similar to the overall prevalence of heart failure among both genders in the Rotterdam population and the Reykjavik Study.514–516

Considerably less is known about the prevalence of the combination of diabetes and heart failure. The most recent and extensive data on the prevalence of diabetes and heart failure are from the Reykjavik Study, showing that the prevalence of the combination heart failure and diabetes is 0.5% in men and 0.4% in women, increasing with increasing age. Heart failure was found in 12% of those with diabetes compared with only 3% in individuals without diabetes. Thus, there was a strong association between diabetes and heart failure.516

Incidence of heart failure and glucose abnormalities

Among British outpatients, the incidence of heart failure has been reported to be around 4/1000 person-years, rising with age. Similar data have been reported from Finland.517,518

Less information is available on the incidence of the combination of diabetes and heart failure. In the Framingham Study, the incidence of heart failure was double among males and five times higher in females with diabetes during 18 years of follow-up, compared with patients free from diabetes515 and in a general population of elderly Italians the incidence of diabetes was 9.6% per year in heart failure patients.520

Prognostic implications

In the presence of diabetes and heart failure, the prognosis becomes deleterious.521 Diabetes is also a serious prognostic factor for cardiovascular mortality in patients with LV dysfunction due to ischaemic heart disease.522 In a general population in Reykjavik, the survival decreased significantly with the concomitant presence of both heart failure and glucose abnormalities, even after adjustment for cardiovascular risk factors and ischaemic heart disease.523 This may be seen as an indicator of the serious implication of the combination of diabetes and heart failure.

Treatment

There are very few, if any, clinical trials on heart failure treatment specifically addressing the diabetic patients. Information on treatment efficacy of various drugs is therefore based on diabetic subgroups included in various heart failure trials. A disadvantage of this is that the subgroups are not always well defined as regards the diabetic state and treatment. Most data favour a proportionately similar efficacy in patients with and without diabetes. Traditional treatment of heart failure in diabetic patients is currently based on diuretics, ACE-inhibitors, and BBs, as outlined in other guidelines.420,506 Moreover, it is assumed that meticulous metabolic control should be beneficial in heart failure patients with diabetes.524

ACE-inhibitors

The use of ACE-inhibitors is indicated both in asymptomatic myocardial dysfunction and symptomatic heart failure, since
they improve the symptoms and reduce mortality. ACE-inhibitors are beneficial in moderate to severe heart failure (Table 22) with and without diabetes.\textsuperscript{525–529} Diabetics represent a rather large subgroup of the patient cohorts in several important heart failure trials. The Studies of LV Dysfunction (SOLVD) Study showed a similar effect of enalapril treatment in patients with compromised LV function, with and without diabetes\textsuperscript{530} and in the Assessment of Treatment with Lisinopril and Survival (ATLAS) Trial, the mortality reduction was at least as good in the diabetic as in the non-diabetic group when comparing high and low doses of lisinopril.\textsuperscript{531} The third Gruppo Italiano per lo Studio della Sopravvivenza nell’Infarto miocardico (GISSI 3) and the Survival and Ventricular Enlargement (SAVE) Trials have shown beneficial effects on mortality and morbidity of ACE-inhibitor treatment in diabetic patients after MI.\textsuperscript{532,533} Hypoglycaemia has been reported following the institution of ACE-inhibitors in patients with diabetes on glucose-lowering treatment.\textsuperscript{534,535} It is therefore recommended to monitor plasma glucose carefully in the early phase of the institution of an ACE-inhibitor in such patients.

**Recommendation**

ACE-inhibitors are recommended as first-line therapy in diabetic patients with reduced LV dysfunction with or without symptoms of heart failure. Class I, Level of Evidence C.

**Angiotensin-II-receptor blockers**

Angiotensin receptor blockers can be used as an alternative to ACE-inhibitors to improve morbidity and mortality in heart failure patients or even in combination with ACE-inhibitor in symptomatic heart failure patients.\textsuperscript{506} The use of angiotensin receptor blockers has not been tested primarily in patients with heart failure and diabetes, but in subgroup analysis of large clinical trials the beneficial effects were equivalent to that of ACE-inhibitors.\textsuperscript{536–538}

**Recommendation**

Angiotensin-II-receptor blockers have similar effects in heart failure as ACE-inhibitors and can be used as an alternative or even as added treatment to ACE-inhibitors. Class I, Level of Evidence C.

**Beta-blockers**

Beta-blockade decreases myocardial free fatty acid exposure, thereby changing that metabolic pathway in type 2 diabetes.\textsuperscript{539,540} There are no studies that specifically address the use of beta-blockade in patients with diabetes and heart failure. Subgroup analysis of diabetic patients in large heart failure trials has, however, shown that BBs reduce mortality and improve symptoms in moderate to severe heart failure to a similar extent in patients with and without diabetes. Since mortality is considerably higher among diabetic than non-diabetic heart failure patients, the number needed to treat to save one life is substantially less in the diabetic cohort. The following BBs may, based on the outcome of clinical trials including subgroups of patients with diabetes, be recommended as first-line treatment in patients with heart failure and diabetes: Metoprolol (MERIT-HF), Bisoprolol (CIBIS II), Carvedilol (COPERNICUS and COMET).\textsuperscript{432,541–545}

**Recommendation**

BBs in the form of metoprolol, bisoprolol, and carvedilol are recommended as first-line therapy in diabetic patients with heart failure. Class I, Level of Evidence C.

**Diuretics**

Diuretics are mandatory for relief of symptoms that are due to fluid overload. These drugs should, however, not be used in excess since they induce neuro-hormonal activation.\textsuperscript{506} Although no studies specifically look into the outcome of the use of diuretics in a heart failure population consisting of diabetic patients, loop diuretics, rather than diuretics which may impair the glucometabolic state further, are recommended.\textsuperscript{546}

**Recommendation**

Diuretics, in particular loop diuretics are important for symptomatic treatment of patients with fluid overload due to heart failure. Class IIa, Level of evidence C.

**Aldosterone antagonists**

The addition of aldosterone antagonists is indicated in severe forms of heart failure and may then improve longevity.\textsuperscript{547} No specific information is, however, available from clinical trials on the administration of aldosterone antagonists in patients with diabetes and heart failure. The institution of blockers of the renin–angiotensin–aldosterone system should be made with caution and surveillance of kidney function and potassium, since nephropathy is not infrequent among patients with diabetes and heart failure.

**Recommendation**

Aldosterone antagonists may be added to ACE-inhibitors, BBs, and diuretics in diabetic patients with severe heart failure. Class IIb, Level of Evidence C.

Glucose lowering treatment and metabolic modulation

Insulin
The main effect of insulin is to decrease blood glucose but it may also increase myocardial blood flow, decrease heart rate, and cause a modest increase in cardiac output.\textsuperscript{548,549} Insulin treatment in patients with diabetes and heart failure is under debate. It has been shown to have beneficial effects on the myocardial function, but also to be associated with increased mortality.\textsuperscript{540,550} Further studies are needed to establish the specific role of insulin treatment beyond the role as an anti-diabetic agent in patients with diabetes and heart failure.\textsuperscript{553–556}

Metabolic modulators
Thiazolidinediones
Thiazolidinediones are insulin sensitizers that are used as glucose-lowering drugs in the treatment of diabetes. Because of a risk for fluid retention, and thereby worsening of heart failure symptoms, the use of these drugs are considered contraindicated in heart failure patients in New York Heart Association Class III–IV.\textsuperscript{552} They may, however, if needed, be attempted in patients with milder degrees of heart failure, New York Heart Association Class I–II.

Diabetes, AF, and risk of stroke

Diabetes and AF
AF is the most common arrhythmia and one of the most important risk factors for stroke.\textsuperscript{557} The prevalence of AF is estimated at 0.4% of the general population and it increases with age.\textsuperscript{558} It is uncommon under 50 years of age, but it reaches a prevalence of ~10% in individuals over 80 years.\textsuperscript{559} The incidence of AF is less than 0.1% per year in subjects under 40 years of age and increases to 1.5% per year in women and 2% in men over 80 years of age.\textsuperscript{560} AF is more frequent in patients with structural heart disease, i.e. heart failure and valvular disease, but a significant proportion occurs in subjects with no history of CVD.

Diabetes is not infrequent in patients with AF. Among patients in the Etude en Activité Libre sur le Fibrillation Auriculaire (ALFA) Study reporting on AF in patients seen in general practice, the proportion of diabetes in patients with chronic AF was 13.1%, making diabetes a common associated condition surpassed only by heart failure and hypertension.\textsuperscript{561} Several cardiac and non-cardiac factors have been demonstrated to have an effect on the incidence of AF. The Manitoba Follow-up Study\textsuperscript{562} estimated the age-specific incidence of AF in 3983 males, to identify risk factors for the development of this arrhythmia. Diabetes was significantly associated with AF with a relative risk of 1.82 in the univariate analysis. However, in the multivariate model the association with diabetes was not significant, suggesting that the increased risk of AF in diabetic men may depend on the presence of ischaemic heart disease, hypertension, or heart failure.

In the Framingham Heart Study,\textsuperscript{563} 2090 men and 2641 women, free of a history of AF and between the ages of 55 and 94 years were studied to identify independent risk factors for the arrhythmia, including diabetes. During up to 38 years of follow-up, 264 men and 298 women developed AF. Diabetes was significantly associated with AF in both genders even after adjustment for age and other risk factors (OR, 1.4 for men and 1.6 for women). Although the mechanisms underlying this association remain to be elucidated, diabetes seems to favour the occurrence of AF.

Diabetes and risk of stroke in AF
The risk of ischaemic stroke is significantly increased among patients with AF.\textsuperscript{570} The rate of ischaemic stroke among patients with AF included in primary prevention clinical trials and not treated with anti-thrombotic therapy averaged 4.5% per year,\textsuperscript{567} which is nine times the proportion in patients without AF. The risk of stroke increases with age. As an example, the annual risk increased from 1.5% in subjects aged 50–59 years to 23.5% for those aged 80–89 years in the Framingham Study.\textsuperscript{558,566}

In epidemiological studies, AF has been identified as a risk factor for stroke in both diabetic\textsuperscript{567,568} and non-diabetic patients. The prevalence of diabetic patients varies from 8 to 34% in observational studies and in primary and secondary stroke prevention trials in patients with AF.\textsuperscript{569–574}

The role of risk factors for stroke among patients with AF not receiving antiocoagulants has been studied in subjects participating in several randomized trials of anti-thrombotic therapy. The AF Investigators (AFI) group\textsuperscript{565} analysed the data from the pooled control groups of five primary prevention trials with warfarin or aspirin in patients with AF. The purpose of the analysis was to identify clinical features indicative of a high vs. low risk of stroke. At the time of randomization, 14% of patients had diabetes. Risk factors that predicted stroke in multivariate analyses of control patients were increasing age, history of hypertension, previous
transient ischaemic attack (TIA) or stroke, and diabetes. Specifically, a diagnosis of DM was an independent risk factor for stroke with a relative risk of 1.7.

The rate of embolic events originating from the atrium in patients with AF increases with the reduction of left atrial appendage flow velocity and the presence of echo contrast at transoesophageal ultrasound examination. A relation between the number of additional risk factors in patients with AF, including diabetes, and the presence of echo contrast or reduced flow velocity in left atrial appendage has been demonstrated, suggesting that factors like hypertension and diabetes may influence the complex thrombo-embolic mechanisms.

**Anti-thrombotic therapy in AF**

Anti-thrombotic therapy prevents stroke in patients with AF. A meta-analysis of 16 randomized clinical trials on 9874 patients was performed to characterize the efficacy of anticoagulant and antiplatelet agents for prevention of stroke in AF. Oral anticoagulation was effective for primary and secondary prevention of stroke in studies comprising 2900 patients, with an overall 62% reduction of relative risk (95% CI: 48–72%). The ARR was 2.7% per year for primary prevention and 8.4% for secondary prevention.

Major extracranial bleedings were increased by anticoagulant therapy by 0.3% per year. Aspirin reduced stroke by 22% (95% CI: 2–38%) with an ARR of 1.5% per year for primary prevention and 2.5% per year for secondary prevention. In five trials, comparing anticoagulant therapy with antiplatelet agents in 2837 patients, warfarin was more efficacious than aspirin with an RRR of 36% (95% CI: 14–52%). These effects were observed in both permanent and paroxysmal AF.

Although warfarin is superior to aspirin for reducing stroke in patients with AF, the absolute and RRR are determined by the initial risk for stroke. High-risk patients, with stroke rates greater than 4% per year, show a larger RRR by oral anticoagulation compared with aspirin, whereas the RRRs are smaller in patients with lower stroke rates. Accordingly, oral anticoagulation is most beneficial for patients at higher risk for stroke, whereas the risks outweigh the benefit in patients at low risk. Thus, quantifying the risk of stroke is crucial for determining which AF patients would benefit most from anticoagulant therapy.

**Diabetes and stroke risk stratification schemes**

Different stroke risk stratification schemes have been proposed for patients with AF and in most of them diabetes is taken into consideration as an important risk factor for stroke. Patients are considered at low, moderate, and high risk of stroke in relation to age, previous stroke, or TIA and the presence of additional risk factors, such as hypertension, diabetes, CAD, and heart failure. However, the importance of diabetes as a risk factor for stroke differs among the stratification schemes. In the AFI scheme, diabetic patients are considered at high risk, independent of age. In the American College of Chest Physicians (ACCP) scheme, they are classified at moderate risk and high risk only if another risk factor is present, whereas diabetes is not included as a risk factor in the Stroke Prevention in AF III Study (SPAF) scheme. Two recently developed schemes are based on scores: the CHADS2 (acronym derived from the individual stroke risk factors: Congestive heart failure, Hypertension, Age >75 years, Diabetes, prior Stroke, or TIA) and the Framingham scheme. In CHADS2, two points were given for prior stroke or TIA (hence, the '2'), and one point was assigned for each of the other factors. In the Framingham scheme, a point system based on age (0–10 points), gender (6 points for female; 0 for male), blood pressure (0–4 points), DM (4 points), and prior stroke or TIA (6 points) was developed. A prospective cohort study tested the predictive accuracy of these five-stroke risk stratification schemes by pooling individual data from 2580 participants with non-valvular AF, who were prescribed aspirin in five multicentre trials on anti-thrombotic therapy. All schemes predicted stroke, but the number of patients categorized as low- and high-risk varied substantially. AF patients with prior cerebral ischaemia were classified as high risk by all five schemes and low-risk patients were also identified by all schemes. However, only CHADS2 successfully identified primary prevention patients who were at high risk of stroke. Of note is that the presence of diabetes is an important contributor in the risk stratification of this scheme. In the 2006 guidelines on AF from the American College of Cardiology/American Heart Association/European Society of Cardiology (ACC/AHA/ESC) task force, diabetes is classified as a moderate risk factor together with age >75 years, hypertension, heart failure, and a LVEF <35%.

**Anti-thrombotic therapy in diabetic patients**

Both the AHA/ACC/ESC guidelines for AF and the American College of Chest Physicians recommend anti-thrombotic therapy for all patients with AF, apart for those with contraindications. The choice of anti-thrombotic agent should be based on the relative risk and benefit for the individual patient, considering the absolute risk for stroke and bleeding with various treatment modalities. In patients with permanent or paroxysmal AF who already had a stroke or a TIA, anticoagulant therapy with an INR between 2.0 and 3.0 is indicated, independently of age or the presence of additional risk factors. Also patients with more than one moderate risk factor for thrombo-embolism, whereof diabetes is one, should receive anticoagulant therapy.

In patients considered to be at increased risk for bleeding (e.g. >75 years of age) but without clear contraindications to oral anticoagulation, a lower INR target of 2.0 (range 1.6–2.5) may be considered.

Recommendations for anti-thrombotic therapy in AF in the presence of only one moderate risk factor is, according to the 2006 AHA/ACC/ESC guidelines, aspirin 81–325 mg daily or anticoagulant therapy. Aspirin is indicated in a dose of 325 mg daily as an alternative in patients with contraindications to oral anticoagulation. In all patients with AF in whom anticoagulant therapy is indicated, INR should be determined at least weekly at the beginning of therapy and monthly when the patient is stable.

Overall and although data from multicentre randomized studies investigating the role of anticoagulants or aspirin in the prevention of stroke in patients with diabetes and AF are not available, it seems appropriate to conclude that diabetes is a risk factor for stroke and that this should be taken into account in the decision on appropriate therapy.
Sudden cardiac death

Epidemiology of sudden cardiac death in diabetes

Sudden cardiac death is a major cause of mortality in the Western population, with ischaemic heart disease as the most important substrate. The presence of co-morbidities identifies the subgroup of patients who are at a high risk. Diabetes is a marker of adverse prognosis in patients after an MI. Although there are no doubts on the excess of total mortality of patients with diabetes after MI, more debate surrounds the issue of whether diabetes increases sudden cardiac death and conflicting results are present in the literature.

Some methodological considerations have to be made before entering in the evaluation of the evidence present in the medical literature. Sudden death is a very difficult end-point to be assessed in clinical trials because of several methodological reasons. First of all, the definition of sudden cardiac death may vary substantially from one study to another, additionally the modality of death (sudden or not sudden) may be ‘arbitrary’ especially when death is unwitnessed and finally the methodology used to define the cause of death (autopsy vs. death certificate vs. whatever information is available) may also determine important differences in the percentage of death labelled as sudden cardiac. When investigating the link between diabetes and sudden cardiac death, the methodological difficulties doubles as the definition of glucose intolerance/diabetes may vary among different studies, thereby affecting the proportion of ‘diabetic’ patients present in various studies. Having made these considerations, the presence of discrepancies between results in the different studies that have investigated the role of diabetes as a risk factor for sudden cardiac death will appear less surprising. Interestingly, however, it appears that studies with large series of patients with very long follow-up (>20 years) support the existence of a positive association between diabetes and sudden cardiac death.

The Framingham Study was one of the first sources of long-term follow-up investigating risk factors for sudden cardiac death in the population. Diabetes was associated with an increased risk of sudden cardiac death in all ages (almost four-fold) and the sudden death risk ratios associated with diabetes were consistently greater in women than men. The importance of diabetes as a risk factor for sudden cardiac death in women was recently investigated by data from the Nurses’ Health Study, which included 121701 women aged 30 to 55 followed for 22 years. It was reported that sudden cardiac death occurred as the first sign of heart disease in 69% of cases, even if almost all the women who died suddenly had at least one cardiac risk factor. Diabetes was a very strong risk factor, as it was associated with almost a three-fold increased risk of sudden death, as compared with hypertension that was associated with a 2.5-fold increased risk and obesity with a 1.6-fold increased risk. These data confirm that diabetes is a strong risk factor for sudden cardiac death in both genders. Interestingly, data are also available to demonstrate that diabetes increases the relative risk for sudden cardiac death in different ethnic groups. The Honolulu Heart Programme investigated the role of diabetes as a pre-disposing factor in middle aged Japanese-American men followed for 23 years. This study showed an increased relative risk for sudden cardiac death in subjects with diabetes and glucose intolerance, as compared with the non-diabetic individuals. It was concluded that prevention of diabetes should be regarded as a measure to reduce sudden cardiac death, not only because diabetes predisposes to MI, but also because it increases risk for arrhythmic death. More recently, the investigators of the Paris Prospective Study demonstrated that, the risk of sudden cardiac death, but not that of fatal MI, was increased in patients with diabetes as compared with those without. Similarly, the Group Health Cooperative presented a large study including 5840 individuals and reinforced the view that diabetes is a strong risk factor for sudden cardiac death in a French population. It seems logical to conclude that most of the evidence concurs to support the concept that diabetes is a risk factor for sudden cardiac death.

Pathophysiology of SCD in diabetes

Diabetic patients have a higher incidence of cardiac arrhythmias, including ventricular fibrillation and sudden death. The causes underlying the increased vulnerability of the electrical substrate in these patients are unclear and it is likely to be the consequence of the interplay of several concomitant factors. (i) Atherosclerosis and (ii) microvascular disease are increased in patients with diabetes and they concur to the development of ischaemia that pre-disposes to cardiac arrhythmias. (iii) Diabetic autonomic neuropathy leads to abnormal reflexes and innervation of the diabetic heart influencing electrical instability. (iv) The electrocardiogram of diabetic patients presents repolarization abnormalities manifesting as prolonged QT interval and altered T waves that may reflect abnormal potassium currents. It seems therefore likely that factors like CAD, direct metabolic alterations, ion channel abnormalities, and autonomic dysfunction may all contribute to create the substrate for sudden cardiac death in the diabetic heart. However, since Ewing et al. proposed that diabetic neuropathy may be a major determinant of electrical vulnerability of the heart in diabetes, several lines of research were activated which supported the view that altered heart rate variability, alteration of QTc interval, and abnormal respiration were all arrhythmogenic consequences of abnormal cardiac innervation and that diabetic neuropathy indeed is a key link between diabetes and excess of sudden cardiac death. Most of these investigations were, however, single-centre studies lacking prospective evaluation or large and representative cohorts of patients. Their aim was to show that autonomic neuropathy was a risk factor for sudden cardiac death. They did not engage in the evaluation of whether it remained an independent risk factor for arrhythmic
death when adjusting for different covariates. Accordingly, the role of autonomic neuropathy as a major determinant of sudden cardiac death has recently been questioned and novel approaches to the problem have emerged from large observational studies.

In a study by Jouven et al., the investigators moved away from the evaluation of the risk of sudden cardiac death in ‘diabetic’ vs. ‘non-diabetic’ patients instead focusing on the relative risk of sudden cardiac death in groups of patients with different values of glycaemia. The study showed, that the higher the values of glycaemia, the higher the risk of SCD. Following adjustment for age, smoking habits, systolic blood pressure, heart disease, and glucose-lowering treatment, even patients with borderline diabetes defined as non-fasting glycaemia between 7.7 and 11.1 mmol/l (140 and 200 mg/dl), had an increased risk of sudden cardiac death (OR 1.24 compared with patients with normoglycaemia). The presence of microvascular disease, defined as retinopathy or proteinuria, and female gender increased the risk of sudden cardiac death in all groups. This study importantly emphasizes that glucose intolerance seems to be a continuous variable directly related to the risk of sudden cardiac death, rather than supporting the previous view of risk being related to a specific threshold of glucose intolerance as suggested by the ‘dichotomous’ approach of comparison between ‘diabetic’ vs. ‘non-diabetic’ patients. This fits with the present concept that cardiovascular risk increases well below present thresholds for diabetes and at glucose levels that usually have been considered fairly normal.

The Framingham Investigators studied the influence of glucose levels on heart rate variability in a large community-based population. They demonstrated that, after adjusting for covariates, indexes of reduced heart rate variability were influenced by plasma glucose. High glycaemic levels were followed by a lower heart rate variability. Similar findings were reported by the Atherosclerotic Risk in Community Study (ARIC), that showed that even the pre-diabetic patients already have abnormalities of autonomic cardiac function and altered heart rate variability. These two studies confirmed that glucose levels should be considered as a continuous variable influencing the autonomic control of the heart. Unfortunately, these studies were not designed to answer the question whether reduced heart rate variability in diabetic patients is an independent predictor of sudden cardiac death. At present, this pressing question remains unanswered.

The Rochester Diabetic Neuropathy Study was designed to define the risk factors for sudden cardiac death and the role of diabetic autonomic neuropathy in a population of 462 diabetic patients followed for 15 years. In a univariate analysis, many covariates were statistically associated with sudden cardiac death including older age, HDL cholesterol, nephropathy stage, creatinine, microalbuminuria and proteinuria, previous MI, prolonged corrected QT, bundle branch block, and a composite autonomic severity score, among several others. Interestingly, necropsy findings demonstrated that all victims of sudden cardiac death had signs of coronary artery or myocardial disease and a bivariate analysis showed that autonomic dysfunction QTc and HDL lost their significant association with sudden cardiac death after adjusting for nephropathy. Overall, the data from this study suggest that kidney dysfunction and atherosclerotic heart disease are the most important determinants of the risk of sudden cardiac death while neither autonomic neuropathy nor QTc are independent predictors of the risk for sudden cardiac death. Unfortunately, this study did not include heart rate variability among the parameters introduced in multivariate analysis. Thus, robust data assessing the value of heart rate variability as an independent predictor of sudden cardiac death in diabetic patients are still lacking.

Based on available evidence, it seems that:

1. Glucose intolerance, even at a pre-diabetic stage, is associated with progressive development of a variety of abnormalities that adversely affect survival and predispose to sudden cardiac death.
2. The identification of independent predictors of sudden cardiac death in diabetic patients has not yet progressed to a stage where it is possible to devise a risk stratification scheme for the prevention of such deaths in diabetic patients.
3. In a single study, microvascular disease and nephropathy have been identified as indicators of increased risk of sudden cardiac death in diabetic patients.

**Recommendations**

Control of glycaemia even in the pre-diabetic stage is important to prevent the development of the alterations that pre-dispose to sudden cardiac death. Class I, Level of Evidence C.

Microvascular disease and nephropathy are indicators of increased risk of sudden cardiac death in diabetic patients. Class IIa, Level of Evidence B.

**Peripheral vascular disease**

**Peripheral and cerebrovascular disease**

bLevel of evidence.*

**Background**

Subjects with diabetes have a two- to four-fold increase in the incidence of peripheral vascular disease and an abnormal ankle–brachial blood pressure index is present in ~15% of such patients. The symptomatic manifestations of peripheral vascular disease are intermittent claudication and
critical limb ischaemia and both these conditions are increased in the diabetic population. Impairment of the circulation in the foot, due to diabetic macro and microvascular disease, is the most common non-traumatic reason for limb amputation. The prevalence of peripheral vascular disease increases with advancing age, duration of diabetes, and peripheral neuropathy. The latter condition may mask the symptoms of limb ischaemia and thus disease progression may be advanced before patients and healthcare providers realize that peripheral vascular disease is present.

Peripheral vascular disease is a marker of general atherosclerosis and patients with both symptomatic and asymptomatic peripheral vascular disease most often also have coronary and/or cerebrovascular disease. Early diagnosis of peripheral vascular disease in diabetic patients is important for the prevention of progression of peripheral vascular disease as well as for prediction of overall cardiovascular risk. The vascular obstructions in subjects with diabetes are often located more distally than in non-diabetic subjects. Thus, the typical diabetic peripheral vascular disease is located in the popliteal artery while decreasing pressure in a cuff placed at the ankle level. The calcification of the media layer of the vessels is also a typical hallmark of diabetic peripheral vascular disease.

Diagnosis

Symptoms of leg ischaemia in diabetic patients with peripheral neuropathy are often atypical and vague. Rather than experiencing pain in legs, the patient may suffer from leg fatigue or only inability to walk at a normal pace. Physical examination is of critical importance for the diagnosis. Palpation of pulses in the leg and visual inspection of the feet are essential. Dependent rubor, pallor when the foot is elevated, absence of hair growth, and dystrophic toenails are signs of peripheral ischaemia.

An objective measure of peripheral vascular disease is the ankle–brachial blood pressure index, defined as the ratio between the arterial pressure at the ankle level and in the brachial artery with the highest pressure. A Doppler device is used to record the pulse in the dorsal pedal artery or the posterior tibial artery, while decreasing pressure in a cuff placed at the ankle level (Figure 15). Measurement is made in the supine position after 5 min of rest. The reproducibility of this method is good and the ankle–brachial blood pressure index should normally be above 0.9. This measurement is valuable for early detection of peripheral artery disease and also for a better stratification of overall cardiovascular risk.

An ankle–brachial blood pressure index below 0.5 or an ankle pressure below 50 mm Hg is indicative of severely impaired circulation of the foot. An ankle–brachial blood pressure index above 1.3 indicates poorly compressible vessels as a result of stiff arterial walls, which usually in diabetic patients are due to atherosclerosis in the media layer of the arterial wall. In situations where a raised ankle–brachial blood pressure index is recorded or a false normal value is suspected, the blood pressure should also be measured at the level of the toe by a minicuff and a technique suitable for blood flow detection in the toe. A patient with critical limb ischaemia is defined as a patient with chronic ischaemic rest pain, ulcers, and gangrene attributable to objectively proven arterial disease. It is important to consider that ulcers may often exist in the diabetic foot despite a normal macrocirculation. These ulcers are then due to disturbances in the microcirculation and most often also to neuropathy. Nevertheless, such ulcers must be dealt with in a meticulous fashion, since gangrene and amputation may result also from this condition.

A thorough investigation, aiming at a detailed description of the anatomy of the vascular obstructions, should only be performed in patients in whom an invasive procedure to restore blood flow is indicated. The method of choice is duplex ultrasound. An arterial angiography should only be performed when it is likely that an invasive intervention to restore arterial circulation may be possible. Alternatives to duplex for determining the localization and degree of obstruction before angiography are segmental pressure measurements or oscillography. Table 23 depicts the different methods for evaluating the peripheral circulation.

should be intensive,286,309,611 as it has been described in detail elsewhere in these guidelines (see section on life style and comprehensive management). Smoking cessation is mandatory and regular exercise is also important. Treatment of hypertension should be vigorous, but in patients with critical limb ischaemia and very low distal perfusion pressures it may be dangerous for the foot to lower blood pressure too much. The survival of tissues in the distal extremities must be prioritized until the critical situation resolves. In such cases, blood pressure should be kept at a level permitting adequate arterial inflow to the distal extremity.

Platelet inhibition with low-dose aspirin, in the magnitude of 75–250 mg/day, is indicated in all patients with type 2 diabetes and CVD who do not have a contraindication and for patients with severe peripheral vascular disease, further inhibition of platelet aggregation by clopidogrel or dipyridamole may be indicated in certain cases, along with anticoagulation with low molecular weight heparin as the first agent of choice.611–614

In patients with non-ischaemic neuropathic ulcers, it is of utmost importance to remove any external pressure from the ulcer area, sometimes necessitating immobilization of the patient in a wheelchair. These ulcers will then most often heal without any intervention directed towards improving the macrocirculation. Careful wound dressing and orthopaedic shoes or appropriate bandaging should be handled by a specialized clinic.610 Unfortunately, many amputations have been performed in cases where careful conservative treatment would have saved the extremity.

**Recommendation**

All patients with type 2 diabetes and CVD are recommended treatment with low-dose aspirin. Class Ia, Level of Evidence B.

In diabetic patients with peripheral vascular disease, treatment with clopidogrel or low molecular weight heparin may be considered in certain cases. Class IIb, Level of Evidence B.

**Revascularization**

If anatomically possible, a revascularization procedure should be attempted in all patients with critical limb ischaemia.609 This can be performed by means of a percutaneous transluminal angioplasty or as a surgical procedure, preferably a bypass with the saphenous vein as the conduit. Percutaneous transluminal angioplasty is the method of choice if short-segment stenoses occur in proximal segments above the knee. Proximal percutaneous transluminal angioplasty can be combined with a more distal bypass operation. Patients with intermittent claudication should be revascularized if they have disabling symptoms and proximal vessel disease.609 For patients with claudication, who need a bypass to the lower leg vessels, a more conservative approach is indicated.

**Recommendation**

Patients with critical limb ischaemia, should if possible, undergo revascularization procedures. Class I, Level of Evidence B.

**Medical treatment of critical limb ischaemia**

The only pharmacological agent so far convincingly shown to have a positive influence on the prognosis of patients with critical limb ischaemia is a synthetic prostacyclin (Ilomedin, iloprost), which is given intravenously daily for a period of 2–4 weeks. In a meta-analysis, rest pain and ulcer size improved in comparison with placebo. More importantly, the probability of being alive with both legs still intact after 6 months was 65% in the iloprost-treated group, compared with 45% in the placebo-treated patients.615

**Recommendation**

An alternative treatment for patients with critical limb ischaemia not suited for revascularization is prostacyclin infusion. Class Ila, Level of Evidence A.

**Stroke**

<sup>b</sup>Level of evidence.

**Background**

The relative risk for stroke is increased in subjects with diabetes by a factor of 2.5–4.1 for men and 3.6–5.8 for women.76,616,617 After correction for other risk factors for stroke, which are more common in diabetic subjects, the risk still remains increased more than two-fold meaning that DM is a strong independent risk factor for stroke.83,618 The relationship between hyperglycaemia per se and stroke is, however, much less clear than the relationship between hyperglycaemia and MI. Diabetic complications such as proteinuria, retinopathy, and autonomic neuropathy further increase the risk for stroke.619,620

The type of stroke is usually ischaemic and the ratio between ischaemic and haemorrhagic stroke is higher in diabetic subjects than in the general population.621
Further, diabetes is an independent risk factor for death from stroke.\textsuperscript{87,622} A TIA has been shown to predict the occurrence of a stroke within 90 days, thus underlining the severity of TIA especially in diabetic patients.\textsuperscript{623}

**Prevention of stroke**

Measures to prevent stroke should include a multifactorial strategy\textsuperscript{629} aimed at treatment of hypertension, hyperlipidaemia, microalbuminuria, hyperglycaemia, and the use of antiplatelet medication, as outlined elsewhere in these guidelines (see also section on hypertension). Results from the HOPE Study and Perindopril Protection Against Recurrent Stroke Study (PROGRESS) suggest that the reduction of stroke incidence in diabetic subjects during treatment based on ACE-inhibitors was greater than would be anticipated from the blood-pressure-lowering effect alone and the effect was also evident in normotensive individuals.\textsuperscript{373,624} In the Losartan Intervention For Endpoint reduction in hypertension Study (LIFE) Trial the same trend was found with an angiotensin receptor blocker.\textsuperscript{378} However, in several other trials, including Anti-hypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), there was no apparent benefit of one class of anti-hypertensive drug over another in this respect.\textsuperscript{380,384}

Treatment with statins has been shown to reduce the incidence of stroke in high-risk patients, but the diabetic sub-populations in the trials have most often been too small to allow a reliable subgroup analysis. In the HPS, a sizeable subgroup of 5963 diabetic patients were randomized to placebo or 40 mg of simvastatin daily. Simvastatin reduced the incidence of stroke by 24%,\textsuperscript{344} Antiplatelet therapy has also been shown to reduce the incidence of stroke in diabetic patients and is indicated for both primary and secondary prevention of stroke.\textsuperscript{625} Aspirin in a low dose (75–250 mg daily) should be the initial choice, but in case of intolerance clopidogrel 75 mg once daily should be given.\textsuperscript{438,613} In patients with recurrent stroke, a combination of aspirin and dipyridamol should be considered.\textsuperscript{626,627} The alternative combination with aspirin and clopidogrel seems less safe since it was associated with an increased risk of bleeding without any benefit in terms of cardiovascular outcome in the MATCH-Trial, performed in 7599 patients of whom 68% had diabetes.\textsuperscript{628} Further, in the CHARISMA-Study, no benefit was evident from long-term dual antiplatelet therapy with aspirin and clopidogrel.\textsuperscript{629} In patients with AF, anticoagulant therapy should be given for stroke prevention as is outlined in the section of arrhythmias–AF and sudden cardiac death.\textsuperscript{630}

The high frequency of early stroke following TIA indicates investigation within 7 days of the index event to reduce the risk of a subsequent, and potentially more serious, neurological event. Evaluation with echocardiography and carotid ultrasound is indicated. An increase in cerebral microemboli is detectable by transcranial doppler (TCD) and high microembolic loads appear to be surrogate markers for future neurological events.\textsuperscript{641} After a TIA or stroke caused by carotid-artery disease, medical treatments can be optimised in risk patients, avoiding the need for emergency carotid surgery allowing patients to undergo safer elective surgery.\textsuperscript{632} Carotid endarterectomy for the prevention of stroke in patients with high-grade stenosis of the carotid artery has been shown to be effective, although it has not been specifically investigated in diabetic patients.\textsuperscript{633} Since complications during and after this procedure are more frequent in diabetic as compared with non-diabetic subjects, special consideration should be paid to the overall risk for peri- and post-operative morbidity and mortality when deciding on surgical interventions in the patient with diabetes.\textsuperscript{633} An alternative to endarterectomy, carotid artery angioplasty and stenting (CAS), which has been found to be at least not inferior to endarterectomy, may prove to be a preferable method in high risk patients.\textsuperscript{634}

**Recommendation**

Normalization of blood pressure is recommended in all patients with diabetes for the prevention of stroke. Class I, Level of Evidence A.

For stroke prevention, blood pressure lowering is more important than the choice of drug. Inhibition of the renin–angiotensin–aldosterone system may have additional benefits beyond blood pressure lowering per se. Class IIa, Level of Evidence B.

Inhibition of the renin–angiotensin–aldosterone system may be considered also in diabetic patients with normal blood pressure levels. Class IIa, Level of Evidence B.

Patients with stroke should be treated with statins according to the same principles as non-diabetic subjects with stroke. Class I, Level of Evidence B.

Antiplatelet therapy with aspirin is recommended for primary and secondary prevention at stroke. Class I, Level of Evidence B.

**Treatment of acute stroke**

The treatment in the acute phase of stroke in diabetic patients should follow the same principles that govern the treatment of stroke in the general population. Thrombolysis is an effective treatment for ischaemic stroke if instituted within 3–4 h.\textsuperscript{635} It reduces mortality and disability from stroke but is associated with a risk of haemorrhage and its use and effects in diabetes require further evaluation by registration in an existing quality registry (SITS-MOST: www.acutestroke.org).

Conservative treatment of stroke includes close surveillance of vital functions, optimization of circulation and metabolic conditions, including glycaemic control, in a stroke ward.\textsuperscript{636} Patients should receive early neurological rehabilitation and correction of abnormalities as outlined above in the section of prevention of stroke. Recent studies suggest that early intervention against hypertension during the acute phase of stroke may be beneficial but currently it is recommended to acutely reduce only very high blood pressures, above 220 mm Hg systolic and/or 120 mm Hg diastolic, and then with great caution not lowering blood pressure to levels that may enhance ischaemia. Blood pressure should not be lowered by more than 25% during the first day of treatment.\textsuperscript{637}

**Recommendation**

Patients with acute stroke and diabetes should be treated according to the same principles as stroke patients without diabetes. Class IIa, Level of Evidence C.

Optimization of metabolic conditions including glycaemic control should be considered as in any other acute disease condition. Class IIa, Level of Evidence C.

bLevel of evidence.

The evolution of intensive care medicine during the last three to four decades has fostered a tremendous increase in the immediate survival of patients suffering from previously lethal, acute insults. Hence, patients now frequently enter a chronic phase of critical illness during which they remain dependent on vital organ support for a more or less extended time period. Mortality has remained high among these prolonged critically ill patients with, on an average, a 20% risk of death. Non-resolving multiple organ failure is the most frequent cause of death and occurs regardless of the initial disease for which admission to the intensive care unit (ICU) was required. Post-operative hyperglycaemia control with intensive insulin therapy in critically ill patients clearly proved to be beneficial with regard to mortality and morbidity of the patients, irrespective of previously diagnosed diabetes.645 Since it is not clear yet whether glucose levels should also be controlled pre- or peri-operatively, we here focus on the impact of this therapy during the patient’s stay in the ICU.

Hyperglycaemia and outcome of critical illness

The stress imposed by critical illness leads to the development of metabolic and endocrine abnormalities. The patients usually become hyperglycaemic, due to insulin resistance and accelerated glucose production, known as ‘stress diabetes’ or ‘diabetes of injury’.638,639 In the acute phase of critical illness, hepatic glucose production is enhanced by upregulation of both gluconeogenesis and glycogenolysis, although serum levels of insulin, which normally suppresses these pathways, are high. Increased levels of glucagon, cortisol, growth hormone, catecholamines, and cytokines all play a role.640–645 Apart from stimulated glucose production, impaired peripheral insulin-mediated glucose uptake contributes to the hyperglycaemic state. The exact pathophysiology of hyperglycaemia during prolonged critical illness remains less clear.

For a long time, it had been accepted that stress-induced hyperglycaemia in critically ill patients is beneficial to organs that largely depend on glucose for their energy supply but do not require insulin for glucose uptake. However, several recent studies clearly identify hyperglycaemia as an important risk factor in terms of mortality and morbidity of these patients. A meta-analysis on patients with MI revealed a strong and consistent association between the development of stress hyperglycaemia and increased risk of in-hospital mortality, and congestive heart failure (CHF) or cardiogenic shock.646 Even mild elevations of fasting glucose levels in patients with CAD undergoing PCI have been associated with a substantial mortality risk.647 Furthermore, the glucose level of patients undergoing CAGB appeared to be an important predictor of delayed extubation.648 A retrospective analysis of a heterogeneous population of critically ill patients also revealed that even a modest degree of hyperglycaemia was associated with substantially increased hospital mortality.649

Approximately 30% of these patients were admitted to the ICU for cardiac indications. Another report studying the occurrence of hyperglycaemia among critically ill children with widely varying pathology and of which 24% had undergone cardiovascular surgery, showed a correlation with higher in-hospital mortality and increased length of stay.650 Similarly, hyperglycaemia predicted increased morbidity and mortality after stroke,651 severe brain injury,652,653 trauma,654,655 and severe burn injury.656

Blood glucose control with intensive insulin therapy in critical illness

A landmark prospective, randomized, controlled study on a large group of patients admitted to the ICU predominantly after extensive surgery or for complications developing after extensive surgery revealed major clinical benefits of intensive insulin therapy during critical illness.442 In the conventional insulin therapy group, only excessive hyperglycaemia above 11.9 mmol/L (215 mg/dL) was treated with insulin, aiming to keep concentrations between 10.0 and 11.1 mmol/L (180–200 mg/dL). This protocol resulted in mean blood glucose levels of around 8 to 9 mmol/L (150–160 mg/dL), i.e. hyperglycaemia. Insulin was administered to the patients in the intensive insulin therapy group to maintain blood glucose levels between 4.4 and 6.1 mmol/L (80–110 mg/dL) and resulted in mean blood glucose levels of around 5 to 6 mmol/L (90–100 mg/dL) i.e. normoglycaemia, without detectable risk of hypoglycaemia-induced adverse events. The baseline characteristics, including the admission glucose levels and the percentage of patients with previously diagnosed diabetes, were comparable for the two treatment groups. Tight blood glucose control with insulin strikingly lowered the mortality during the period in the ICU from 8.0 to 4.6% (43% reduction). This benefit was most pronounced among patients who required intensive care for more than 5 days, with an ICU mortality reduction from 20.2 to 10.6% and an in-hospital mortality reduction from 26.3 to 16.8%. More than 60% of the total patient population was included after cardiac surgery. In this subgroup, intensive insulin therapy reduced ICU mortality from 5.1 to 2.1%. Of the long-stay cohort of patients, approximately one-third was admitted to the ICU after cardiac surgery.

Besides saving lives, intensive insulin therapy largely prevented several critical illness-associated complications.445 The incidence of critical illness polyneuropathy was reduced by 44%, the development of blood stream infections by 46%, and acute renal failure requiring dialysis or haemofiltration by 41%. The need for red blood cell transfusions was a median 50% lower, indicating that anaemia developed less frequently. Patients were also less dependent on prolonged mechanical ventilation and intensive care. The clinical benefits of this therapy were equally present in most diagnostic subgroups, including the cardiac patients. For the latter
subgroup, a follow-up study showed that intensive insulin therapy also improved long-term outcome, when given for at least a third day in ICU, with maintenance of the survival benefit up to 4 years after randomization. Risk for hospital re-admission and dependency on medical care were similar in both groups. The short-term glycaemic control with insulin during intensive care did not induce a substantial burden for the patient, his/her relatives or society, although the perceived quality of social and family life appeared to be moderately compromised. Particularly in the patients with isolated brain injury, intensive insulin therapy protected the central and peripheral nervous system from secondary insults and improved long-term rehabilitation.

Importantly, the Leuven protocol of glycaemic control in a predominantly surgical patient population was recently proven, in a large RCT, to be similarly effective in a strictly medical ICU patient population. In the intention-to-treat group of 1200 patients, morbidity was significantly reduced, with lower occurrence of newly developed kidney injury, earlier weaning from mechanical ventilation, and earlier discharge from the ICU and from the hospital. The latter patients also developed hyper-bilirubinaemia less frequently. There was no difference in bacteraemia or prolonged antibiotic therapy requirement but the number of long-stay patients with hyper-inflammation was reduced. In the intention-to-treat group, insulin therapy did not significantly alter mortality (in-hospital mortality from 40.0 to 37.3%, P = 0.3). This was not surprising, as the study was not powered for this mortality endpoint. In the target group of long-stay patients, defined as receiving at least a third day of intensive care for which the study was powered, intensive insulin therapy reduced in-hospital mortality from 52.5% in the conventional therapy requirement but the number of long-stay patients also developed hyper-bilirubinaemia less frequently. There was no difference in bacteraemia or prolonged antibiotic therapy requirement but the number of long-stay patients with hyper-inflammation was reduced. In the intention-to-treat group, insulin therapy did not significantly alter mortality (in-hospital mortality from 40.0 to 37.3%, P = 0.3). This was not surprising, as the study was not powered for this mortality endpoint. In the target group of long-stay patients, defined as receiving at least a third day of intensive care for which the study was powered, intensive insulin therapy reduced in-hospital mortality from 52.5% in the conventional to 43.0% in the intensive insulin therapy group (P = 0.009) and reduced morbidity even more strikingly.

An earlier observational study also largely confirmed the clinical benefits of the surgical ICU Trial in ‘real-life’ intensive care of a heterogeneous medical/surgical population. In this study, the impact of implementing a tight glucose management protocol was documented, comparing the new outcome results with historical controls. Approximately 18% of the patients were referred to intensive care for a cardiac diagnosis. In this study, blood glucose control was somewhat less strict, as intensive insulin therapy aimed for glucose levels below 7.8 mmol/L (140 mg/dL) and intravenous insulin was only administered if glucose levels exceeded 11.1 mmol/L (200 mg/dL) on two successive measurements. In this way, mean glucose levels of 8.4 mmol/L (152 mg/dL) in the baseline period decreased to 7.3 mmol/L (131 mg/dL) in the protocol period. After the implementation of the protocol, hospital mortality was 29% lower, length of intensive care stay 11% lower, whereas 75% fewer patients developed new renal failure and 19% fewer required red blood cell transfusion. The prevention of severe infections could not be confirmed, but the incidence of this complication was already low in the baseline period. However, another prospective, randomized, controlled study, although small, revealed decreased incidence of nosocomial infections in a predominantly surgical ICU patient population. In this study, intensive insulin therapy targeted glucose levels between 4.4 and 6.7 mmol/L (80–120 mg/dL), resulting in mean daily glucose levels of 6.9 mmol/L (125 mg/dL) vs. 9.9 mmol/L (179 mg/dL) in the standard glycaemic control group. In an observational study of patients with DM undergoing cardiac surgery, intravenous insulin infusion to eliminate hyperglycaemia also lowered in-hospital mortality compared with the historical control group, with fewer deep sternal wound infections and shorter length of hospital stay.

Whereas it has clearly been demonstrated that tight glucose control is achievable and safe in post-operative and medical ICU patients, peri-operative glycaemic control during cardiopulmonary bypass appears to be much more difficult, at times unattainable, and carries a high risk of inducing post-operative hypoglycaemia. However, another group was successful in reliably maintaining normal glucose levels during open heart surgery by using the hyperinsulinaemic normoglycaemic clamp technique. A summary of different trials on intensive insulin therapy in critical illness is given in Table 24.

Strict blood glucose control with intensive insulin therapy improves mortality and morbidity of adult critically ill patients. Class I, Level of Evidence A.

**Mechanisms behind improved outcome with intensive insulin therapy**

Multivariate logistic regression analysis indicated that hyperglycaemia and a high dose of insulin were associated with a high risk of death.665 Hence, it was the blood glucose control, and/or other metabolic effects of insulin that accompany tight blood glucose control, and not the insulin dose administered per se that contributed to the improved survival with intensive insulin therapy. The association between high insulin dose and mortality is likely explained by more severe insulin resistance in the sicker patients who have a high risk of death. The risk of death indeed appeared to linearly correlate with the degree of hyperglycaemia, with no clear cut-off below which there was no further benefit.665 Patients who received conventional insulin therapy and who developed only moderate hyperglycaemia (6.1–8.3 mmol/L or 110–150 mg/dL) had a lower risk of death than those with severe hyperglycaemia (8.3–11.1 mmol/L or 150–200 mg/dL), whereas they were at higher risk of death than patients whose blood glucose levels were controlled below 6.1 mmol/L (110 mg/dL) with intensive insulin therapy. Other data also suggest that the mortality benefits can be attributed to glycaemic/metabolic control, rather than the absolute insulin doses administered.649,666 For the prevention of critical illness polyneuropathy, bacteraemia, anaemia, and acute renal failure, tight glycaemic control below 6.1 mmol/L (110 mg/dL) similarly appeared to be of crucial importance.665

If indeed avoiding hyperglycaemia is crucial, it appears striking that by doing so only for the relatively short period, during the patient’s need for intensive care, this strategy prevented the most feared complications of critical illness. Normal cells protect themselves from moderate hyperglycaemia by downregulation of glucose transporters.667 On the other hand, chronic hyperglycaemia causes complications in diabetic patients in a time frame which is several orders of magnitude longer than the time it took to prevent life-threatening complications during intensive care. Thus, hyperglycaemia appears more acutely toxic in critically ill patients than in healthy individuals or diabetic patients. Upregulation of insulin-independent glucose uptake, mediated by the glucose transporters GLUT-1, GLUT-2, or GLUT-3 and resulting in cellular glucose overload, may play a role.668 Part of the improvement with intensive insulin therapy is therefore likely explained by preventing glucose toxicity to the mitochondrial compartment,669 the endothelium,670 the neurons,658 and immune cells.671 However, also other effects of insulin may contribute to improved outcome, including the partial correction of the abnormal serum lipid profile,672 the prevention of excessive inflammation,673,674 and counter-action of the catabolic state evoked by critical illness.669,675 Although data from different studies appear controversial, administration of insulin in a GIK regimen has shown to improve myocardial function and to protect the myocardium during AMI, open heart surgery, endotoxic shock, and other critical conditions.674,675 However, the recent large randomized CREATE-ECLA Trial on GIK infusion in patients with AMI and the DIGAMI-2 Trial in patients with diabetes and AMI failed to show an effect of this intervention on survival, cardiac arrest, and cardiogenic shock.326,444 Although direct anti-apoptotic properties of insulin, independent of glucose uptake, and involving insulin signalling have been shown to play a role in the described cardioprotective action of insulin,674 such effects may be counteracted by elevated levels of blood glucose.674 As such, lack of glucose control in the CREATE-ECLA and the DIGAMI-2 Trial might explain the controversy surrounding GIK using different protocols.326,444,678 Adequately designed studies are therefore needed to fully assess the efficacy of GIK for myocardial protection and to dissect the impact of glycaemic control from that of insulin.

**Cost-of-illness studies**

The most widely used method to assess the burden of diabetes is through cost-of-illness studies, which strives to assess the total cost caused by a disease or condition.679,680 A search for cost-of-illness studies in diabetes, published in the English language, was performed by searching Medline, Embase, and HEED (the Health Economics Evaluation Database). Most published studies were performed in the US,581–688 although some studies investigated the situation in European countries. These are summarized in Table 25. With the recognition of diabetes as a global disease, there have been a number of studies published for other countries as well.689–694

Most cost-of-illness studies have not made a distinction between type 1 and type 2 diabetes. This is unfortunate, since the two types of the disease affect different age groups and require different management. Another difficulty when comparing the results from different studies is that different methodological approaches may give different results. This has several explanations: (i) there is uncertainty about the incidence and prevalence of the disease, (ii) studies use different methods for attributing costs, (iii) different cost items have been included, (iv) evaluation principles differ, (v) data includes measurement error, and (vi) there are different approaches to estimate the cost of diabetes, e.g. including all costs for patients with diabetes gives a higher estimate than including only the costs attributable to diabetes and its complications, which in turn gives a higher estimate than only including costs due to the diagnosis diabetes as such.705

The CODE 2 Study706 was designed to measure the total healthcare costs for patients with type 2 diabetes in eight European countries using the same methodological...
approach. Patients from Belgium, France, Germany, Italy, the Netherlands, Spain, Sweden, and the UK were included. The study used a bottom-up, prevalence-based design, which means that all healthcare costs for diabetes patients were collected. Due to the strong impact of co-morbidity in type 2 diabetes patients, it is not possible to separate which resource use is due to diabetes and which is due to other diseases. This can only be done with epidemiological methods, comparing patients with and without diabetes. Efforts were made to ensure consistency in terms of data collection, analysis, and reporting of results, which means that this study gives an opportunity for international comparisons. Table 26 shows the total cost per country, the cost per patient and the share of healthcare costs accounted for by patients with diabetes.

The total healthcare cost for patients with diabetes in the eight countries amounted to 29 billion Euro. Per capita cost varied from 1305 Euro per patient in Spain to 3576 Euro in Germany. In addition, the estimated share of total healthcare costs varied significantly between countries, indicating that despite striving for the same method of data collection, there may have been differences between how the study was conducted in different countries. The very low figure for the Netherlands may reflect lower costs, but more probably a selection bias in the patients studied and/or a too low estimate of the prevalence of type 2 diabetes. Differences in the definition of healthcare expenditures between countries may also be a factor to consider when analysing the differences between countries.

### The cost-effectiveness of intervention

Knowledge about the cost of a disease is not sufficient information to guide us when making a decision on how to treat it. To do that, we need information about the cost of the intervention, and about the expected health effects. In other words, we need information about the cost-effectiveness of the interventions. There have been many studies investigating the cost-effectiveness of different treatment strategies for diabetic patients. Here we will focus on the prevention of macrovascular complications, as they are the largest contributor to the costs associated with the disease.

Lipid-lowering using statins in diabetics have been studied in several studies. In a subgroup of the 4S Trial, cost-effectiveness ratios of treating diabetic patients with 20–40 mg simvastatin were found to be well below the levels that are usually considered cost-effective. The key driver of this increase in costs was a higher cost for hospitalization among patients with complications. This is natural, since patients are not frequently hospitalized for their diabetes, whereas macrovascular complications, such as MI, lead to immediate hospitalization. The total prevalence of macrovascular complications was 33%, with 12% of patients having a history of heart failure, 9% of MI, and 17% of the patients suffering angina pectoris.

Table 26 shows the distribution of the direct costs on different cost items. Hospitalizations are the largest cost component in the sample as a whole as well, once again indicating the importance of complications. It is interesting to note that cardiovascular drugs are the single most important category of drugs, accounting for about one-third of drug costs. This is more than the costs of insulin and oral diabetic drugs together.

It is important to realize that the CODE-2 Study only captures part of the cost of the diabetes, as only direct healthcare costs are included. Lost production, caused by sick absence, early retirement, and early mortality also carries high costs. In studies that have included this component, it sums up to more than 50% of the total costs.

The results from the CODE-2 Study show that the main cost-driver in diabetes is not the disease as such or the treatment of diabetes, but rather the complications caused by diabetes. In the study, patients were divided into complication-free, having microvascular complications only, having macrovascular complications only, or having both macro and microvascular complications. In these three groups, the relative costs were 1.7, 2.0, and 3.5 times higher than the costs among patients without complications. The key driver of this increase in costs was a higher cost for hospitalization among patients with complications. This is natural, since patients are not frequently hospitalized for their diabetes, whereas macrovascular complications, such as MI, lead to immediate hospitalization. The total prevalence of macrovascular complications was 33%, with 12% of patients having a history of heart failure, 9% of MI, and 17% of the patients suffering angina pectoris.

Another approach to prevention of macrovascular complication is through blood pressure control. This has been studied as part of the UKPDS, where tight blood pressure control is through blood pressure control. This has been shown to reduce the risk of cardiovascular events. As the most important cost drivers are complications caused by the disease, proper management in the prevention of complications is essential.

**Appendix**

**Glossary of abbreviations and acronyms**

AACE, American Association of Clinical Endocrinologists; ACC, American College of Cardiology; ACCP, American College of Chest Physicians; ACS, Acute Coronary Syndromes; ADA, American Diabetes Association; ADP, Adenosine Diphosphate; AGEs, Advanced Glycation End Products; AHA, American Heart Association; ALFA, Activéité Libérale sur la Fibrillation Auriculaire; AMI, acute myocardial infarction; ARB, angiotensin receptor blocker; ATP, adenosine triphosphate; BB, beta-blocker; BMI, body mass index; CABG, coronary artery bypass grafting; CAD, coronary artery disease; CAS, carotid artery angioplasty and stenting; CCB, calcium channel blocker; CI, confidence interval; COX-2, cyclooxygenase-2; CPG, Committee for Practice Guidelines; CS-D, cardiac surgery in diabetes patients; CV, cardiovascular; CVD, cardiovascular disease(s); DAG, diacylglycerol; DBP, diastolic blood pressure; DES, drug eluting stents; DM, diabetes mellitus; DMF, diabetes determined by fasting plasma glucose ≥7.0 mmol/L and 2-h plasma glucose <11.1 mmol/L; DMP, diabetes determined by 2-h plasma glucose ≥11.1 mmol/L and fasting plasma glucose <7.0 mmol/L; EASD, European Association for the Study of Diabetes; ECG, electrocardiogram; EGIR, European Group for the Study of Insulin Resistance; eNOS, endothelial nitric oxide synthase; ESC, European Society of Cardiology; F; female; FFA, free fatty acid; FPG, fasting plasma glucose; GAD, glutamic-acid-decarboxylase; GIK, glucose–insulin–potassium; GLUT, glucose transporters; HbA1c, glycated haemoglobin; HDL, high-density lipoprotein; HEED, Health Economics Evaluation Database; HF, heart failure; HOT, hypertension optimal treatment; HR, hazard ratio; ICU, intensive care unit; IDF, International Diabetes Federation; IFG, impaired fasting glucose/glycaemia; IGR, impaired glucose regulation; IGTT, impaired glucose tolerance test; IL, interleukin; INR, International normalized ratio; LDL, low-density lipoprotein; M, male; MAPP, mitogen-activated protein kinase pathway; MCP-1, monocyte chemotactant; MI, myocardial infarction; MODY, maturity-onset diabetes in the young; NADPH Ox, nicotinamide adenine dinucleotide phosphate oxidase; NCEP, National Cholesterol Education Programme; NIDDK, National Institutes of Diabetes, Digestive, and Kidney Diseases; NNT, numbers needed to treat; NO, nitric oxide; NOS, nitric oxide synthase; NSTEMI, non-ST-elevation myocardial infarction; OGTT, oral glucose tolerance test; ONOO-, peroxynitrite; PAI, plasminogen activator inhibitor; PCI, percutaneous coronary interventions; PGI2/TXB2, prostacyclin/thromboxane; PIGS, prostacyclin synthase; PI-3K, phosphatidylinositol-3 kinase; PKC, protein kinase; PLC, phospholipase; PI-3K, phosphatidylinositol-3 kinase; RITA, randomized intervention treatment of angina; ROS, reactive oxygen species; RR, risk ratio; SCD, sudden cardiac death; SD, standard deviation; SK, streptokinase; SPECT, single-photon emission computed tomography; STEMI, ST-elevation myocardial infarction; TC, total cholesterol; TCD, transcranial Doppler; TG, triglyceride; Thr, thrombin; TIA, transient ischaemic attacks; TNF, tumour necrosis factor; TPA, tissue plasminogen activator; Tz, thiazide; TZD, thiazolidinediones; UA, unstable angina pectoris; VLDL, very low-density lipoprotein; WHO, World Health Organization; DECODE Study, Diabetes Epidemiology: Collaborative Analysis of Diagnostic Criteria in Europe; 4S, Scandinavian Simvastatin Survival Study; ABCD, Appropriate Blood Pressure Control in Diabetes; ACCORD, Angioplasty Coronary, Corvalias and Diltiazem; ACE-I, angiotensin converting enzyme-inhibitor; ADDITION study, Anglo-Danish-Dutch Study of Intensive Treatment and Complication Prevention in Type 2 Diabetic Patients Identified by Screening in Primary Care; ALLHAT, Anti-hypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial; ARIC, Atherosclerotic Risk in Community Study; ARTS, Arterial Revascularisation Therapy Study; ASCOT, Anglo-Scandinavian Cardiac Outcomes Trial; ASCOT-LLA, Anglo-Scandinavian Cardiac Outcomes Trial-Lipid Lowering Arm; ATLAS, Assessment of Treatment with Lisopronil and Survival; ATP III,
Adult Treatment Panel III; AWESOME, Angina with Extreme Serious Operative Mortality Evaluation; BARI, Bypass Angioplasty Revascularization Investigation; CABRI, Coronary Angioplasty vs. Bypass Revascularization Investigation; CAPPP, Captopril Prevention Project; CAPRIE, Clopidogrel vs. Aspirin in Patients at Risk of Ischaemic Events; CARDia, Coronary Artery Revascularization in Diabetes Trial; CARDS, Collaborative Atorvastatin Diabetes Study; CARE, Cholesterol and Recurrent Events Substudy; CHADS, Congestive heart failure, Hypertension, Age >75 years, Diabetes, prior Stroke or TIA; CHARISMA-Study, Clopidogrel for high atherothrombotic risk and ischaemic stabilisation management and avoidance; CIBIS II, The Cardiac Insufficiency Bisoprolol Study II; CODE 2 Study, Cost of type II Diabetes in Europe; CORD, Carvedilol Randomized Cumulative Survival; COPERNICUS, Carvedilol Prospective Randomized Cumulative Survival; CURE, Clopidogrel in Unstable Angina To Prevent Recurrent Events; DCCT, Diabetes Control and Complication Trial; DIGAMI, Diabetes Glucose And Myocardial Infarction; EAST, Emory Angioplasty vs. Surgery Trial; ECLA, Estudios Cardiologicos Latinoamericanos; EDIC Study, Epidemiology of Diabetes Interventions and Complications; EHS-ACS, The Euro Heart Survey of Acute Coronary Syndromes; EUROASPIRE I, II, European Action on Secondary Prevention through Intervention to Reduce Events I, II; EURODIAB IDDM Complication Study, EURODIAB Insulin Dependent Diabetes Mellitus Complication Study; EUROPA, European Trial on Reduction Of cardiac events with Perindopril in stable coronary Artery disease; HOPE Study, Heart Outcomes Prevention Evaluation; IDDM, Insulin-dependent Diabetes Mellitus; ISAR, Intensive Stimulation and Angioplasty Randomized Trial; FIELD, Fenoibrate Intervention and Event Lowering in Diabetes; FINDRISC, Finnish Diabetes Risk Score; FREEDOM, Future Revascularization Evaluation in Patients with Diabetes Mellitus: Optimal Management of Multivessel Disease; FRISC-II, Fragnhim and Fast Revascularization During Instability in Coronary Artery Disease II; GISSI, Gruppo Italiano per lo Studio della Sopravvivenza nell’ Infarto miocardico; GISSI 3, The Third Group Italiano per lo Studio della Sopravvivenza nell’ Infarto miocardico; GRACE, Global Registry of Acute Coronary Events; GUSTO-I, Global Utilization of Streptokinase and tPA for Occcluded Coronary Arteries-I; GUSTO-IIIb, Global Utilization of Streptokinase and tPA for Occluded Coronary Arteries-IIIb; HDPP, Hypertension Detection and Follow-up Program; HHS, Helsinki Heart Study; HOPE Study, Heart Outcomes Prevention Evaluation; IHD, Intensive Heart Protection Study; INSIGHT, International Nifedipine GITS Study Intervention as a Goal in Hypertension Treatment; LIFE, Losartan Intervention for Endpoint reduction in hypertension Study; MATCH-Trial, Antplatelets in Stroke Prevention; MERIT-HF, Metopropol Randomized Intervention Trial in Congestive Heart Failure; MITRA, Maximal Individual Therapy in Acute myocardial infarction; MONICA, Monitoring trends and determinants in Cardiovascular disease; NHANES II, National Health and Nutrition Examination Survey; NHANES III Study, The Third National Health and Nutrition Examination Survey; NORDIL, The Nordic Diltiazem; OASIS, Organization to Assess Strategies for Ischemic Syndromes; PROACTIVE Trial, a randomized controlled trial of the efficacy of a family-based, domiciliary intervention programme to increase physical activity among individuals at high-risk of diabetes; PROCAM, Prospective Cardiovascular Munster; PROGRESS, Perindopril Protection Against Recurrent Stroke Study; PROVE-IT Trial, Pravastatin or Atorvastatin Evaluation and Infection Therapy; RCT, Randomized Controlled Trial; RIKS-HIA, Register of Information and Knowledge about Swedish Heart Intensive Care Admission; SAVE, Survival And Ventricular Enlargement Study; SHEP, Systolic Hypertension in the Elderly Program; SOLVD, Studies of Left Ventricular Dysfunction; SPATRIAL, Stress Test Prevention in Atrial fibrillation III Study; STENO 2, Cardiovascular Disease and Type 2 Diabetes; STOP-2, Swedish Trial in Old Patients with Hypertension-2; STOP-NIDDM Trial, Study TO Prevent Non-Insulin-Dependent Diabetes Mellitus; SYST-EUR, Systolic Hypertension in Europe Trial Investigators; TNT, Treat to New Targets Trial; UKPDS, United Kingdom Prospective Diabetes Study; VAHIT, Veterans Administration HDL Trial; VALIANT, VALsartan In Acute myocardial infarctioN.
